There are different forms of stationarity, depending on which of the random function's statistical characteristics are restricted and the working spatial scale. They include the strict stationarity, the second-order (or weakly or wide-sense) stationarity, the intrinsic stationarity, and the local (or quasi) second-order stationarity. These notions can be found in the following reference books: Cressie (2015), Wackernagel (2013), Chiles and Delfiner (2012), Olea (2012), Christakos (2012), Webster and Oliver (2007), Diggle

and Ribeiro (2007), Goovaerts (1997), and Isaaks and Srivastava (1989).

Formulation

Suppose that the spatially continuous variable of interest is modeled as a random function (also referred to random field or spatial stochastic process) $\{Z(x) : x \in D \subseteq \mathbb{R}^d\}$ defined over a fixed continuous spatial domain of interest $D \subseteq \mathbb{R}^d$, where $\mathbb{R}^d$ is d -dimensional Euclidean space, typically $d = 2$ (plane), and $d = 3$ (space).

The random function $Z(\cdot)$ is said to be strictly stationary if its spatial distribution is invariant under translations, that is to say,

$$F_{x_1, \dots, x_k}(v_1, \dots, v_k) = F_{x_1+h, \dots, x_k+h}(v_1, \dots, v_k) \quad (1)$$

for all integers $k \in \mathbb{N}^*$, collections of points $x_1, \dots, x_k$ in the spatial domain D , set of possible values $v_1, \dots, v_k$, and vectors $h \in \mathbb{R}^d$; in which F denotes finite-dimensional joint distributions defined by $F_{x_1, \dots, x_k}(v_1, \dots, v_k) = P(Z(x_1) \leq v_1, \dots, Z(x_k) \leq v_k)$.

Under the strict stationarity assumption, finite-dimensional joint distributions characterizing the spatial distribution of the random function stay the same when shifting a given set of points from one part of the study domain to another. In other words, a translation of a point configuration in a given direction does not change finite-dimensional joint distributions. Thus, the random function appears as homogeneous and self-repeating in the whole spatial domain. The strict stationarity assumption is very restrictive because it assumes an identity of all probability distributions in the space. Moreover, it is only partially verifiable since it is made for all $k \in \mathbb{N}^*$, and it does not tell us about the existence of moments of the random function.

The random function $Z(\cdot)$ is said to be second-order (or weakly or wide-sense) stationary if its first- and second-order moments exist and are both invariant under translations over the spatial domain D , i.e., $\forall x, x+h \in D$,

$$E(Z(x)) = E(Z(x+h)) \quad (2)$$

$$\text{Cov}(Z(x+h), Z(x)) = C(h) \quad (3)$$

Thus, under the second-order stationarity, the expected value (or mean) of the random function is constant, i.e., the same at any point x of the spatial domain D . The covariance function which measures the second-order association between any pair of points depends only on the separation between them in both distance and direction. When a random function is second-order stationary, its first- and second-order moments are also said to be stationary. The second-order

stationarity implies the existence not only of the mean and the covariance function but also other second-order moments such as the variance, the variogram, and the correlogram: $\forall x, x+h \in D$,

$$\text{Var}(Z(x)) = \text{Cov}(Z(x), Z(x)) = C(0) \quad (4)$$

$$\frac{1}{2} \text{Var}(Z(x+h) - Z(x)) = C(0) - C(h) = \gamma(h) \quad (5)$$

$$\frac{\text{Cov}(Z(x+h), Z(x))}{\sqrt{\text{Var}(Z(x)) \times \text{Var}(Z(x+h))}} = \frac{C(h)}{C(0)} = \rho(h) \quad (6)$$

In particular, when $h = 0$, the covariance comes back to the ordinary variance which must also be constant. Stationarity of the covariance implies stationarity of variance, and the variogram, and the correlogram. These moments also do not depend on the absolute position of the points where they are calculated but only on their separation. The second-order stationarity assumption requires the existence of the covariance function which might not exist.

The strict stationarity requires all the moments of the random function (if they exist) to be invariant under translations. In particular, the strict stationarity implies the weak stationarity when the mean and the covariance function of the random function exist. These two forms of stationarity are equivalent if the random function is Gaussian. Indeed, since a Gaussian distribution is completely defined by its first two moments, knowledge of the mean and the covariance function suffices to determine the spatial distribution of a Gaussian random function. Overall, weak stationarity is less restrictive than strict stationarity. Moreover, it turns out that the weak stationarity condition is sufficient for most of the statistical results derived for spatial data to hold. For these reasons, weak stationarity is employed more often than strict stationarity. Various authors use the term stationarity to refer to weak stationarity.

The random function $Z(\cdot)$ is called intrinsically stationary if for any vector $h \in \mathbb{R}^d$, the increment (or difference) $\{Z_h(x) = Z(x+h) - Z(x) : x \in D \subseteq \mathbb{R}^d\}$ is a second-order stationary random function. Specifically,

$$E(Z(x+h) - Z(x)) = 0 \quad (7)$$

$$\begin{aligned} \text{Var}(Z(x+h) - Z(x)) &= E\left((Z(x+h) - Z(x))^2\right) \\ &= 2\gamma(h) \end{aligned} \quad (8)$$

The intrinsic stationarity focuses on the second-order stationarity of the increments of the random function. It is less restrictive than the second-order stationary. Indeed, the second-order stationarity implies the intrinsic stationarity.

The converse is not necessarily true. The intrinsic stationarity hypothesis expands the second-order stationarity hypothesis which no longer relates to the increments of the random function. The intrinsic stationarity is the reason that the variogram has emerged as the preferred measure of spatial association in geostatistics. The variogram can still be defined for cases where the covariance function and the correlogram cannot, and it does not require knowledge of the mean. The covariance function of an intrinsic stationary random function might not exist; it exists only if the variogram is bounded, in which case one has the relation,

$$\gamma(h) = C(0) - C(h) \quad (10)$$

Thus, under the second-order stationarity, it is equivalent to work with the covariance function or the variogram, one deduced from the other by the above relation. Classical Brownian motion in one dimension (or Wiener process) provides an example of a Gaussian random function that is intrinsically stationary, but not second-order stationary. It has independent and stationary Gaussian increments, and its variogram is given by $\gamma(h) = |h|$ while its covariance function is expressed as follows: $\text{Cov}(Z(s), Z(t)) = \min(s, t), s, t > 0$. Examples of realizations of second-order and intrinsically stationary random functions defined on the unit square are given in Fig. 1.

The different forms of stationarity presented previously do not explicitly involve the working spatial scale, which is nevertheless an essential parameter in practice. A model valid at a particular spatial scale may no longer be valid at larger or smaller spatial scales. In most applications (especially prediction problems), it is not useful for second-order stationary or intrinsically stationary assumptions to be valid at the scale of the whole spatial domain, but only for distances less than a certain limit distance. Thus, they do not require global stationarity, but only local stationarity.

A random function is said to be locally (or quasi) second-order stationary if its mean is a very regular function varying slowly in space such that $E(Z(x+h)) \approx E(Z(x))$ if $\|h\| \leq b$ ($b > 0$), and its covariance function $\text{Cov}(Z(x+h), Z(x))$ only depends on the vector h for distances $\|h\| \leq b$ ($b > 0$). Such random functions, which are not necessarily second-order stationary at the scale of the whole spatial domain, have a smooth mean function, which can be evaluated locally as a constant and a covariance function which can be considered locally as stationary.

Under the local (or quasi) second-order stationarity assumption, the statistical inference of the first- and second-order moments requires in practice to have enough data locally. Thus, the local second-order stationarity hypothesis is therefore a trade-off between the size of the neighborhood where the random function can be considered as stationary

Stationarity, Fig. 1 (a) example of realization of a second-order stationary random function; and (b) example of realization of an intrinsically stationary random function

and the number of data necessary to perform a reliable statistical inference.

In addition to the stationarity assumption, isotropy assumption is often added, which extends the notion of translational invariance of stationarity by including rotational invariance (around the origin). In other words, the covariance function (or variogram) is simply a function of the Euclidean distance, i.e., $C(h) = C(\|h\|)$ or $\gamma(h) = \gamma(\|h\|)$. One then calls both the random function and the covariance function (or variogram) isotropic. Thus, stationarity means translation-invariance of the statistical properties of the random function, while isotropy is a corresponding rotation-invariance.

Limitations

The assumption that all or some statistical characteristics of the random function are translation invariant over the whole spatial domain may be appropriate, when the latter is small in size, when there is not enough data to justify the use of a complex model, or simply because there is no other reasonable alternative. Although often justified and leading to a reasonable analysis, this assumption is often inappropriate and unrealistic given certain spatial data collected in practice. Stationarity assumption can be doubtful due to many factors, including specific landscape and topographic features of the study region or other localized effects. These local influences are reflected in the fact that observed data can obey to a

covariance function (or variogram) whose characteristics vary across the study domain. In such a setting, a stationary assumption is not appropriate because it could produce less accurate predictions, including an incorrect assessment of the prediction error. Hence, the need to go beyond the stationarity.

When the stationary assumptions do not hold, we are in the non-stationarity framework which means that some statistical characteristics of the random function are no longer translational invariant; they depend on the location. A random function that does not have the stationarity property is called nonstationary. One distinguishes different types of nonstationarity: nonstationarity in mean, nonstationarity in variance, and nonstationarity in covariance (or variogram). It is now recognized that most spatial processes exhibit a nonstationary spatial dependence structure when considering large distances. A detailed discussion on nonstationary random functions and the various models can be found in Fouedjio (2017). Figure 2 shows two examples of realizations of nonstationary random functions defined on the unit square.

Diagnostic Tools

The random function's modeling choice, either in the stationary framework or the nonstationary framework, is a fundamental decision to make during geostatistical analysis. A common practice to check for the second-order stationarity assumption is to informally assess plots of local experimental variograms computed at different subregions across the study

Stationarity, Fig. 2 Two examples of realizations of nonstationary random functions

region. If the different local experimental variograms are bounded and do not differ notably, the assumption of second-order stationarity may be reasonable. Although a useful diagnostic tool, this graphical tool is challenging to assess and open to subjective interpretations.

Hypothesis tests of the assumption of second-order stationarity may be more valuable. However, it is not straightforward to build such tests in the context of a single realization of the random function. Very few formal procedures to test for the second-order stationarity have been developed (Fuentes 2005; Jun and Genton 2012; Bandyopadhyay and Rao 2017). They are adaptations of stationarity tests for time series. Most of them are built up based on the spectral representation of the random function. They consist essentially of testing either the homogeneity or the uncorrelatedness of some variables defined in the frequency or spectral domain. Some of the testing procedures check both for stationarity and isotropy.

Summary and Conclusions

In geostatistics, the spatially continuous variable of interest is modeled as a random function and the observed data as the random function's unique realization. To infer the statistical characteristics of the spatial distribution of the random function from observed data, limiting assumptions are needed. They appeal to the notion of stationarity of the random function. It enables us to treat observed data as though they have the same degree of variation over a region of interest. Several stationary assumptions are possible: strict stationarity, second-order (or weakly or wide-sense) stationarity, intrinsic stationarity, and local (or quasi) second-order stationarity.

Although stationarity assumptions are often violated in practice, they remain fundamental. They form the basic building blocks of more complex models, such as second-order nonstationary random function models. Indeed, in most of these models, the stationarity assumption is present, either locally or globally. The majority of second-order nonstationary random function models include some stationary random function models as special cases. Hence, the concept of stationarity plays a critical role in geostatistics. Although it is challenging to accept or reject a stationarity hypothesis in the context of a single realization of the random function, some diagnostic tools can help to decide whether this assumption is appropriate or not. Moreover, the relevance of a stationarity hypothesis can depend on the working spatial scale considered.

In this entry, the concept of stationarity has been presented in the case of a scalar random function for univariate spatially continuous data. However, it extends to the case of a vector-valued random function (i.e., set of scalar random functions stochastically correlated to one another) for multivariate spatially continuous data.

Statistical Bias

Gilles Bourgault
Computer Modelling Group Ltd., Calgary, AB, Canada

Definitions

- | | |
|-----------------|--|
| Sampling Bias | In its basic definition, statistical bias is simply the difference in values between a statistic that is estimated from a sample and its equivalent characterizing the entire population. It is an intrinsic sampling error that affects all statistics estimated from the partial sampling of a population. |
| Estimation Bias | In a spatial context (geostatistics), a statistical estimate is localized in space, and multiple estimates are required for spatial estimation from a given sampling. Because all non- |

sampled locations are equivalent in regards of statistical estimation, it is the set of estimated values that can be considered for statistical bias. The estimated values will, in general, show a statistical bias in their distribution shape (less variance and less skewness) and in their spatial continuity (greater spatial continuity) when compared to the population values. For spatial estimation, the estimation bias is combined to the sampling bias.

Estimate and Estimator

For any population statistical parameter (θ), and its estimate (θ^*) from a sample, the statistical bias is the difference.

$$\text{Bias} = \theta^* - \theta \quad (1)$$

This difference measures the statistical bias for a given sampling. It cannot be avoided and fluctuates from sampling to sampling. The most important factor affecting this statistical bias is the sample size since the statistic θ^* will converge towards the population value as the sample size increases. But in practice, this statistical bias can never be known from a single sampling since populations are always very large and can never be sampled exhaustively. Instead of correcting the statistical bias, one tries to minimize it. It calls on the unbiasedness of the estimate when it is viewed as a random variable (estimator). The sample estimator (θ^*) is said to be unbiased, if on average over many samplings, the expected value of the statistical bias is zero.

$$E[\theta^* - \theta] = 0 \quad (2)$$

Or equivalently, the expected value of the estimator is equal to the population parameter.

$$E[\theta^*] = \theta \quad (3)$$

For example, from a sample of n values (z_i), the estimator

$$\bar{z} = \frac{\sum_{i=1}^n z_i}{n} \quad (4)$$

is unbiased for estimating the mean of the population (Z).

$$E[\bar{z}] = E[Z] \quad (5)$$

The unbiasedness of an estimator is easily demonstrated by replacing each sample value (z_i) with an equivalent random variable (Z_i), and assuming $E[Z_i] = E[Z]$ for all Z_i .

Estimator Quality

An estimator can be biased or unbiased and of variable precision. For a biased estimator, its expected value, over multiple samplings, will be different from the population value ($E[\theta^*] \neq \theta$). Most often, this type of bias would be introduced by a systematic calibration error in the instrumentations, or in the laboratory processes, used to measure each sample value. For an unbiased estimator, its sampling error may be small or large, depending on its precision. The precision is higher when the estimated statistic varies little between samplings. Usually, the precision increases with the sampling size. Some of the most important estimators' characteristics are depicted in Fig. 1. Note that a biased estimator can still be precise without being accurate. Thus, precision does not guaranty accuracy. The precision of an estimator may also depend on the distribution shape of the population values to be sampled. The precision tends to be lower as the skewness of the distribution is more pronounced.

Spatial Estimate and Spatial Estimator

The mean estimator (Eq. 4) for the global population can be adapted for local spatial estimation (geostatistics) when assuming that each location ($\mathbf{u} = [u_x, u_y, u_z]$) is associated with a random variable $Z(\mathbf{u})$. The set of all spatial locations, within a domain of interest, defines the population (Z). Kriging (Matheron 1965; Armstrong 1998) is a spatially weighted average that has been developed as the best linear unbiased estimator (BLUE) for spatial estimation. Multiple types of kriging exist, but ordinary kriging is the most used in practice.

$$z^*(\mathbf{u}_0) = \sum_{\alpha=1}^n \lambda_{\alpha} * z(\mathbf{u}_{\alpha}) \quad (6)$$

where $z^*(\mathbf{u}_0)$ is the kriging estimate at a spatial location $\mathbf{u}_0$, the $z(\mathbf{u}_{\alpha})$'s are the sample values at n locations ($\mathbf{u}_{\alpha}$), and the λ_{α} 's are the kriging weights. The weights are optimum in the sense that they account for spatial correlation (variogram) between the $n + 1$ locations involved (Isaaks and Srivastava 1989). The estimator is unbiased by ensuring that the sum of the weights equals 1, and assuming each sample value $z(\mathbf{u}_{\alpha})$ can be replaced by an equivalent random variable ($Z(\mathbf{u}_{\alpha})$), with same mean as the spatial population ($E[Z(\mathbf{u}_{\alpha})] = E[Z]$ for all locations $\mathbf{u}_{\alpha}$ in the spatial domain). Note that a statistical bias can still be induced, even with an unbiased spatial estimator, when the sampling favors certain locations in the population (i.e., high grade zones in a mineral deposit). Random or systematic samplings can be used to avoid this type of bias.

Statistical Bias, Fig. 1 Schematic representation for the distribution (over multiple samplings) of a biased estimator (left) and the distributions of two unbiased estimators (right). For the unbiased estimators, the

estimator 2 is more precise than estimator 1 since its distribution over multiple random samplings is tighter around the population value (in red)

Transfer Function Bias

Kriging is a particular estimator (Eq. 6) in the sense that it can generate multiple estimated values, one for each non-sampled location in the spatial domain. Because of estimation bias, the set of all estimated values ($\{z^*\}$) will have different statistical properties, such as lower variance and greater spatial continuity (variogram), as compared with the set of their corresponding population values ($\{z\}$). This will, in general, introduce some functional bias.

$$\text{Bias} = f(\{z^*\}) - f(\{z\}) \quad (7)$$

The bias depends on the degree of estimation bias in the set of estimated values, and on the degree of nonlinearity of the function $f()$ (i.e., spatial correlation, metal recovery function in mining, flow simulation in oil and gas). Conditional simulations (Goovaerts 1997; Deutsch and Journel 1998) can minimize this bias by restoring the data variance and the spatial variability in the estimated values. But contrary to the kriging estimates, simulation results are not unique as an infinite number of realizations can be simulated.

Conditional Bias

Spatial estimators are designed to be unbiased globally for the population, $E[Z^*(\mathbf{u}_0)] = E[Z(\mathbf{u}_0)] = E[Z]$. However, they can still be biased, on average over the spatial domain, when considering a particular estimate value. This brings about

the concept of conditional bias. Kriging is such an estimator that is globally unbiased but can be conditionally biased when each estimated location value is compared to the true value at that location (comparing $z(\mathbf{u}_0)$ with $z^*(\mathbf{u}_0)$ for all estimation locations $\mathbf{u}_0$). In the spatial context, a special quality for an estimator is to be conditionally unbiased. On average, over the spatial domain, one expects that the estimator will predict the correct value. Thus, the estimator is conditionally unbiased if

$$E[Z^* \mid Z^* = z^*] = E[Z \mid Z^* = z^*] \quad (8)$$

or equivalently

$$E[Z \mid Z^* = z^*] = z^* \quad (9)$$

where Z^* is the kriging estimator viewed as a random variable, Z the random variable representing the spatial population, and z^* a kriging estimate value. If one averages all true values, for all locations with the same kriging estimate value, then this average should be equal to that kriging estimate value. The conditional expectation is localized in the sense that the kriging estimates with the same given value z^* are localized in space. These locations represent a subset of the population. The expectation is conditional to this subset (Eq. 8). Conditional unbiasedness is very important in mining to best categorize spatial locations as being mineralized or sterile for example. Minimizing conditional bias is at the origin of kriging. It was first addressed by Krige (1951) and revisited by Bourgault (2021).

In the following, statistical biases and non-biases are illustrated for various statistics, and for the kriging estimator, in using samplings from synthetic datasets.

Global Fluctuations for Basic Statistics

The effects of the sampling size and distribution shape on statistical bias are illustrated when sampling two synthetic populations with same mean and variance, but with different distributions. One is characterized with a normal distribution (no skewness) and the other is characterized with a lognormal distribution (highly skewed). Each population has a total of 2500 values that are spatially distributed on a regular 50×50 grid. The lognormal distribution is from the primary variable of GSLIB dataset (Deutsch and Journel 1998). The normal distribution is the lognormal distribution transformed in normal scores and rescaled to have the same mean and same variance as the lognormal distribution. Fluctuations in sampling mean, variance, histogram, and variogram are illustrated for sample sizes of 50, 100, and 200. For each sample size, 11 random samplings were drawn from the population. For each sampling, the same spatial locations were sampled in both populations. Table 1 presents the fluctuations for the sample mean and the sample variance, over the 11 random samplings, for the 3 different sampling sizes, for the lognormal population. Table 2 presents the fluctuations for the sample mean and the sample variance, over the 11 random samplings, for the 3 different sampling sizes, for the normal population.

The results show that statistical bias from sampling can be significant, but on average, the mean and variance are fairly

well estimated for the two populations. The statistical bias fluctuations (precision), as measured by the range and the variance of each statistic, tend to diminish when the sampling size increases. The fluctuations are much less when the population is normally distributed as compared to lognormally distributed, especially for the variance.

Figures 2, 3, and 4 show the histogram for each sampling with the average histogram over the 11 samplings and the histogram of the lognormal population. For each sampling size, the averaged histogram matches very well the true population histogram. However, the fluctuations between the 11 histograms increase as the sample size increases. Figures 5, 6, and 7 show the histogram for each sampling with the average histogram over the 11 samplings and the histogram of the normal population. Again, for each sampling size, the averaged histogram matches very well the true histogram. Contrary to the lognormal population, the fluctuations between the 11 histograms decrease as the sample size increases.

In a spatial context, not only the data histogram is important, but also the data variogram as it needs to be modelled for measuring the spatial correlation required for spatial estimation by kriging (Isaaks and Srivastava 1989). Figures 8, 9, and 10 present the variogram for each sampling with the averaged variogram over the 11 samplings, and the variogram for the lognormal population. For each sampling size, the averaged variogram matches very well the population true variogram. The fluctuations between the 11 variograms diminish somewhat when the sample size increases. However, similar to the sample variance (Table 1), there is not much reduction when increasing the sampling size from 100 to 200. Figures 11, 12, and 13 present the variogram for each sampling with the

Statistical Bias, Fig. 4 Histograms for 11 samplings (s1–s11) of 200 sample values each for the lognormal population. The averaged histogram (in black) can be compared to the true histogram (in red)

averaged variogram over the 11 samplings and the variogram for the normal population. For each sampling size, the averaged variogram matches very well the true variogram. Contrary to the lognormal population, and similarly to the sample variance of the normal population (Table 2), the fluctuations between the 11 variograms diminish significantly when the sample size increases.

Local Fluctuations for Spatial Estimation

For both populations, ordinary kriging was used for spatial estimation (Eq. 6) for all samplings. Figure 14 shows a cross-plot for the true values (z) versus their kriging estimates (z^*) for the sampling size of 50 in the lognormal population. Although the kriging estimates are not globally biased ($E[Z^*] = E[Z]$), they show a regression line with a slope smaller than 1. This is typical for kriging estimates (or any type of linear spatial averaging). The regression line with a slope smaller than 1 indicates that, on average over the field, the kriging estimates tend to over-estimate the true values when the kriging estimates are greater than their global mean, and they tend to underestimate the true values when

they are smaller than their global mean. In terms of conditional expectations (Eq. 9): $E[Z | Z^* = z^*] < z^*$ when $z^* > E[Z^*]$ and the opposite $E[Z | Z^* = z^*] > z^*$ when $z^* < E[Z^*]$. It is only when the kriging estimates are equal to their global mean that the conditional bias disappears as $E[Z | Z^* = E[Z^*]] = E[Z^*] (= E[Z])$ since kriging is globally unbiased). A spatial estimator such as kriging, achieves global unbiasedness at the price of conditional biases. Note that kriging is still the best spatial estimator. Other linear estimators will usually show larger conditional biases (Isaaks and Srivastava 1989). Bourgault (2021) has shown that the slope of the linear regression is 1 (45° line) when a spatial estimator is both, globally (Eq. 3) and conditionally unbiased (Eq. 9). Therefore, the slope value of the linear regression between the true values versus their kriging estimates is a good measure of the degree of conditional bias. Table 3 gives the average, variance, and range of the regression slopes over the 11 samplings for each of the 3 sampling sizes for the lognormal population. Table 4 gives the average, variance, and range of the regression slopes over the 11 samplings for each of the 3 sampling sizes for the normal population.

Results show significant statistical fluctuations between samplings, especially for the lognormal population. For both

Statistical Bias, Fig. 5 Histograms for 11 samplings (s1–s11) of 50 sample values each for the normal population. The averaged histogram (in black) can be compared to the true histogram (in red)

populations, the averaged regression slope increases closer to 1 with the sampling size. Thus, on average, conditional bias diminishes as the sampling size increases. But for all sampling sizes, the regression slope is on average larger, and its range and variance are smaller, for samplings in the normal population. The normal population is less prone to conditional bias than the lognormal population, even if the variance of the estimates is similar for both.

Spatial Correlation

Figure 15 shows the variograms calculated from the 2300 kriging estimates, for each of the 11 samplings of size 200, in the lognormal population. Typically, the curves are lower (less variance), especially near the origin of the plot, when compared to the true variogram of the population. Also, the curves gradient near the origin of the plot becomes smaller than for the true variogram. This is characteristic of a smoother spatial correlation (or greater spatial continuity) (Chiles and Delfiner 2012). Smoothing is a common form of bias in the earth sciences in general and particularly with kriging. Contrary to the averaged variogram from the sample values (Fig. 10), the averaged variogram from the kriging estimates shows a clear bias when compared to the true

variogram. This estimation bias tends to be more severe for kriging estimates from the smaller sampling sizes of 50 and 100 (not shown).

Global Fluctuations for Statistics from Truncated Distributions

Even, if kriging estimates are globally unbiased, and may show minimal conditional bias, another type of statistical bias is yet present. The expected value above a given threshold (t) will be underestimated due to the estimation bias (smoothing) of the kriging estimates (Isaaks 2004; Bourgault 2021). A global bias still exists when truncating the distribution for values above a threshold. This truncation is often required in the practice of mining as not all mineralized spatial locations in the population can be considered economical and should not all be considered for mineral recovery. As an example, Tables 5 and 6 give the expected value for values above the first quartile of the entire population.

As with other statistics, results show significant statistical fluctuations between samplings for both populations. Increasing the sampling size tends to reduce the fluctuations. It is observed that the average expected value, for values above the first quartile over all samplings, is not biased for the sample

Statistical Bias, Fig. 6 Histograms for 11 samplings (s1–s11) of 100 sample values each for the normal population. The averaged histogram (in black) can be compared to the true histogram (in red)

Statistical Bias, Fig. 7 Histograms for 11 samplings (s1–s11) of 200 sample values each for the normal population. The averaged histogram (in black) can be compared to the true histogram (in red)

Statistical Bias, Fig. 8 Variograms for 11 samplings (s1–s11) of 50 sample values each for the lognormal population. The averaged variogram (in black) can be compared to the true variogram (in red)

Statistical Bias, Fig. 9 Variograms for 11 samplings (s1–s11) of 100 sample values each for the lognormal population. The averaged variogram (in black) can be compared to the true variogram (in red)

values (z). However, it is biased (smaller) for the estimated values by kriging (z^*), because the kriging estimates are smoother (less variance ranging from about 15 to 18 from Tables 3 and 4) than the population (26.53 from Tables 1 and 2) (see also Fig. 15).

Correcting Conditional Bias

Bourgault (2021) has shown that conditional bias could be corrected by averaging the kriging estimates over all the random samplings. Tables 7 and 8 provide the regression

Statistical Bias, Fig. 10 Variograms for 11 samplings (s1–s11) of 200 sample values each for the lognormal population. The averaged variogram (in black) can be compared to the true variogram (in red)

Statistical Bias, Fig. 11 Variograms for 11 samplings (s1–s11) of 50 sample values each for the normal population. The averaged variogram (in black) can be compared to the true variogram (in red)

slopes between the true values and the averaged kriging estimates ($\text{avg}(z^*)$), over the 11 random samplings, for each sample size.

From the results of Tables 7 and 8, it is observed that averaging the kriging estimates corrects well the conditional bias for the lognormal distribution but tends to overcorrect

Statistical Bias, Fig. 12 Variograms for 11 samplings (s1–s11) of 100 sample values each for the normal population. The averaged variogram (in black) can be compared to the true variogram (in red)

Statistical Bias, Fig. 13 Variograms for 11 samplings (s1–s11) of 200 sample values each for the normal population. The averaged variogram (in black) can be compared to the true variogram (in red)

(slopes larger than 1) for the normal distribution, especially for the smaller sampling sizes. In such a case, instead of averaging the kriging estimates, it is advised to pick the sampling that is associated with the smaller data variance.

For the normal distribution, the sample with the smallest data variance for sampling size 50 is associated with kriging estimates showing a regression slope of 0.84, 0.86 for sampling size of 100, and 0.91 for sampling size 200. Bourgault (2021)

Statistical Bias, Fig. 14 Cross-plot of true values versus kriging estimates (Z^*) using a sample size of 50 for the lognormal population. The regression line is shown in green, the 45° line is shown in black and the horizontal and vertical lines indicate the global means

Statistical Bias, Table 3 Average, variance, and range for the regression slope between the true values and their corresponding kriging estimates for 11 random samplings of different size (50, 100, 200) of the lognormal distribution. Last row provides the averaged variance for the (n^*) kriging estimates

		$n = 50$	$n = 100$	$n = 200$
Regression slope	Average	0.5	0.62	0.68
	Variance	0.06	0.04	0.04
	Range	0.19–0.9	0.35–0.95	0.36–0.97
Variance of estimates	Average	15.61 ($n^* = 2450$)	14.47 ($n^* = 2400$)	16.17 ($n^* = 2300$)

Statistical Bias, Table 4 Average, variance, and range for the regression slope between the true values and their corresponding kriging estimates for 11 random samplings of different size (50, 100, 200) of the normal distribution. Last row provides the averaged variance for the (n^*) kriging estimates

		$n = 50$	$n = 100$	$n = 200$
Regression slope	Average	0.71	0.82	0.90
	Variance	0.01	0.003	0.002
	Range	0.55–0.94	0.76–0.91	0.84–0.96
Variance of estimates	Average	15.28 ($n^* = 2450$)	16.5 ($n^* = 2400$)	18.57 ($n^* = 2300$)

has shown that, in general, samplings with a smaller data variance are associated with a regression slope closer to 1.0 for their kriging estimates. Comparing Table 7 and Table 3 shows that correcting for conditional bias is associated with an important variance reduction for the estimates (ranging from about 14 to 16 from Table 3 versus ranging from about 5 to 9 for the corrected kriging estimates Table 7).

For the lognormal population, the averaged kriging estimates ($\text{avg}(z^*)$) are not conditionally biased (Eq. 9, Table 7). Thus, they are the best estimates to categorize the spatial locations in terms of ore ($\text{avg}(z^*) > t$) or waste ($\text{avg}(z^*) < t$), for example. This brings back the topic of expected value for truncated distribution ($E[Z | Z > t]$). Table 9 shows

Statistical Bias, Table 5 Average, variance, and range for the average above the population first quartile (Q1) for the sample (z) and the (n*) estimated (z*) values of the population for 11 random samplings

Q1 = 0.34		n = 50	n = 100	n = 200	n = 2500
E[Z Z > Q1]	Average	3.44	3.4	3.51	3.37
	Variance	1.13	0.41	0.13	0
	Range	1.95–5.2	2.39–4.55	2.76–4.07	
E[Z* Z* > Q1]		n* = 2450	n* = 2400	n* = 2300	n* = 0
	Average	3.16	3.0	3.13

	Range	3.19–5.3	3.29–4.33	3.83–4.57	

of different size (50, 100, 200) of the normal distribution. The last column provides the statistic for the entire population

Statistical Bias, Fig. 15 Variograms using the kriging estimates (k1–k11) from the 11 samplings (s1–s11) of sample size 200 in the lognormal population. The averaged variogram (in black) can be compared to the true variogram (in red)

their expected value for values above the first quartile of the true population.

From the results of Table 9, it is seen that $\text{avg}(z^*)$, over the 11 samplings, is not really conditionally biased for estimating $E[Z | \text{avg}(Z^*) > Q1]$. However, it is underestimating $E[Z | Z > Q1] = 3.37$ from the lognormal population. Even if $E[Z |$

$Z > Q1] = 3.37$ is fairly well estimated by the sample data values (Table 5), it is always underestimated by the kriging estimates, and even more so when they are corrected for conditional bias (Tables 5 and 9) to improve the selectivity for locations above or below the threshold (i.e., between ore and waste). Indeed, on average over the 11 samplings, avg

Statistical Bias, Table 7 Regression slope between the true values and their corresponding averaged kriging estimates for 11 random samplings of different size (50, 100, 200) of the lognormal distribution. Last row provides the variance for the averaged kriging estimates over the 2500 spatial locations

	$n = 50$	$n = 100$	$n = 200$
Regression slope	1.07	1.1	1.07

Statistical Bias, Table 8 Regression slope between the true values and their corresponding averaged kriging estimates for 11 random samplings of different size (50, 100, 200) of the normal distribution. Last row provides the variance for the averaged kriging estimates over the 2500 spatial locations

	$n = 50$	$n = 100$	$n = 200$
Regression slope	1.36	1.26	1.14
Variance of estimates	7.76	10.61	14.56

Statistical Bias, Table 9 Average above the population first quartile (Q1) for the averaged kriging estimates for 11 random samplings of different size (50, 100, 200) of the lognormal distribution. The second row provides the conditional expectation for the true values when their corresponding estimates are above the first quartile. The last row provides the averaged conditional expectation, over the 11 random samplings, of the true values when their corresponding kriging estimates are above the first quartile

Q1 = 0.34		$n = 50$	$n = 100$	$n = 200$
$E[\text{avg}(Z^*) \mid \text{avg}(Z^*) > Q1]$		2.87	2.71	2.93
$E[Z \mid \text{avg}(Z^*) > Q1]$		2.59	2.65	2.80
$\text{avg}(E[Z \mid Z^* > Q1])$	Mean	2.81	2.89	2.96
	Range	2.7–2.96	2.8–3.02	2.84–3.17

($E[Z \mid Z^* > Q1]$), for the kriging estimates, is always a bit closer to the true value (3.37) than $E[Z \mid \text{avg}(Z^*) > Q1]$ for the averaged kriging estimates. The underestimation by the averaged kriging estimates has its source in the lower variance for the conditionally unbiased estimates (compare variance of estimates in Tables 3 and 7).

Correcting for Estimation Bias

Some authors (McLennan and Deutsch 2002; Journel and Kyriakidis 2004) have proposed to estimate $E[Z \mid Z > t]$ using conditional simulations (Deutsch and Journel 1998) instead of kriging, since conditional simulations are designed to preserve the data variance in reproducing the sample histogram and variogram. It is a correction of the estimation bias by avoiding smoothing. Bourgault (2021) has shown, that indeed, conditional simulations (Zs) can be used if their resulting statistic ($E[Zs \mid Zs > t]$) is averaged over various samplings. Even if the simulated values do not suffer from the estimation bias, they still suffer from sampling bias just like

the sample histogram and variogram do. But in practice, and unlike the kriging estimates, or averaged kriging estimates, simulations cannot be used to categorize ore and waste on the spatial domain because the simulated values (Zs) cannot be definitively associated with any particular spatial locations as they change for each simulated realization. For recovering the minerals above an economical threshold, $E[Z \mid \text{avg}(Z^*) > t]$ (or $E[Z \mid Z^* > t]$ from the kriging estimates of a particular sampling) can be achieved, but $E[Z \mid Z > t]$ cannot. The statistical bias $E[Z \mid \text{avg}(Z^*) > t] < E[Z \mid Z > t]$ (or $E[Z \mid Z^* > t] < E[Z \mid Z > t]$) cannot be avoided. It can only be estimated, either from the sample values (Tables 5 and 6) or from conditional simulations.

Summary and Conclusions

Statistical estimation fluctuates, from sampling to sampling, leading to statistical bias associated with any given sampling. The fluctuations are more important when the sampling size is smaller, but also if the population has a skewed distribution like it is often the case in earth sciences. Sampling a lognormal population is more sensitive to statistical bias than sampling a normal population. Averaging the statistic of interest over multiple samplings is a proven approach for correcting the statistical bias for basic statistics (average, variance, histogram) and for spatial statistics (variogram). For spatial estimation, estimation bias will be added to the sampling bias. Averaging kriging estimates over multiple samplings ($\text{avg}(z^*)$) can correct for conditional bias, especially when the distribution is highly skewed. Thus, more smoothing, or more estimation bias, helps to reduce conditional bias. This will provide estimated values that will be unbiased for estimating $E[Z \mid \text{avg}(Z^*) > t]$ but will underestimate the true $E[Z \mid Z > t]$. Even if for many statistics their statistical bias can be practically eliminated by averaging them over multiple samplings, the processing of estimated values, or averaged estimated values, by a transfer function will in general provide biased results. For example, the application of a threshold value to mineral estimation will always suffer from some degree of statistical bias due to the smoothing of the estimator ($\text{variance}(\text{avg}(z^*)) \ll \text{variance}(z)$). This is the mining paradox where a variance reduction (smoothing) is required to remove conditional bias, such as to improve selectivity between ore and waste, but also induces a statistical bias in the expected recovery when the ore category is defined by grades above a threshold value.

analysis, resampling methods for the estimation of confidence intervals or hypothesis testing, standard or robust linear regression, compositional data analysis, computational maximum likelihood estimation, nonlinear optimization, and multivariate tools such as principal component analysis. Statistical computing is especially important in the Earth sciences because data tend to be statistically complicated, rarely being described by simple distributions, and because of the proliferation of vast data sets as observing systems expand.

Introduction

It is assumed at the outset that readers of this entry are familiar with elementary probability and statistical concepts, such as set theory, the definition of probability, sample spaces, probability density and cumulative distributions, and measures of location, dispersion, and association, that are covered in the first few chapters of textbooks such as De Groot and Schervish (2011) or Chave (2017a). Some familiarity with standard distributions, such as the Gaussian and chi-square types, is also expected. Statistical computation is implemented in software packages such as Matlab that is widely used in the Earth and ocean sciences, and open source implementations include R and Python with third-party modules.

As noted in the Definition, statistical computing is a vast subject and cannot be covered comprehensively in anything short of a book. The treatment will be limited to exploratory data analysis tools, resampling methods including the bootstrap and permutation tests, linear regression, and nonlinear optimization to implement a maximum likelihood estimator. A more comprehensive treatment of computational data analysis may be found in Chave (2017a), where Matlab implementation is a focus, and at a more advanced level in Efron and Hastie (2016).

Statistical Computing

Alan D. Chave

Department of Applied Ocean Physics and Engineering, Deep Submergence Laboratory, Woods Hole Oceanographic Institution, Woods Hole, MA, USA

Definition

Statistical computing is a broad subject, covering all aspects of the analysis of data or statistical simulation that require the use of some type of computational engine. An incomplete list of statistical computing topics includes exploratory data

Exploratory Data Analysis Tools

Exploratory data analysis comprises the early stages in evaluating a given data set where the goal is their characterization. Let $\{X_i\}$ be a data sample of size N drawn from an unknown probability density function (pdf) $f(x)$. Partition the data range $\{\min(x_i), \max(x_i)\}$ into a set of r bins according to some rule. For example, the rule could partition the data into equal-sized intervals. Count the number of data in each bin. A frequency histogram is a plot of the counts of data in each bin against the midpoint of the bin. Other normalizations can be used, such as transforming counts into probabilities. The outcome is a simple way to characterize a given data set, but it remains

somewhat subjective because the bin sizes and their boundaries are arbitrary.

A better qualitative approach to characterize the distribution of $\{X_i\}$, which are assumed to be independent and identically distributed (iid), is the use of a kernel density estimator, which is a smoothed rather than binned representation of a distribution. The kernel density estimator that represents $f(x)$ is given by

$$\hat{f}(x) = \frac{1}{N\delta} \sum_{i=1}^N K\left(\frac{x - x_i}{\delta}\right) \quad (1)$$

where $K(x)$ is a symmetric kernel function that integrates to one over its support and $\delta > 0$ is the smoothing bandwidth. A number of kernel functions are in use, but the standard Gaussian works well in practice. The smoothing bandwidth δ can be chosen by the user, but for a Gaussian kernel function the optimal value is

$$\delta = \left(\frac{4s_N^5}{3N} \right) \quad (2)$$

where $\hat{s}_N$ is the sample standard deviation. Figure 1a shows a kernel density pdf for 5000 random draws from Gaussian distributions with means of -2 and 2 and a common variance of 1 . The solid line uses (2) to give a smoothing bandwidth of 0.4971 and adequately resolve the peaks from the two Gaussian distributions. It also accurately reproduces the analytical form of the pdf. The dashed line shows the kernel density pdf for $\delta = 0.1$, which overestimates the peak heights and introduces multiple peaks at their top. The dotted line shows the kernel density pdf for $\delta = 2$, which smears the two peaks together.

In many instances, data may be drawn from a distribution whose support is finite, in contrast with the previous example. In this case, the kernel density estimator will give incorrect results unless the kernel density algorithm limits the support. Figure 1b shows a simple example using the arcsine distribution, which is defined only over $(0, 1)$. The arcsine distribution is equivalent to a beta distribution with arguments $(\frac{1}{2}, \frac{1}{2})$. The solid line shows the kernel density pdf when the support is unconstrained. By contrast, the dashed line shows it when the support is limited to $(0, 1)$ and is almost identical to the dotted line that shows the analytical form.

The quantile-quantile or q-q plot enables the assessment of the distribution of a set of data in a qualitative manner and can be made quantitative by adding error bounds based on the Kolmogorov-Smirnov statistic. A q-q plot consists of the quantiles of the target distribution $F^*(x)$ against the order statistics $x_{(i)}$ computed by sorting the sample. The quantiles are those values of the inverse cumulative distribution function at the uniform distribution quantiles:

Statistical Computing, Fig. 1 (left) Kernel density pdf for 5000 random draws from Gaussian distributions with means of -2 and 2 and a variance of 1 . The solid line uses (2) for the smoothing bandwidth, while the dashed and dotted lines use values of 0.1 and 1 , respectively. (right) Kernel density pdf for 500 random draws from the arcsine distribution. The solid line assumes unbounded support, while the dashed line has support of $(0, 1)$. The dotted line is the analytic pdf

$$u_i = \frac{i - 0.5}{N} \quad i = 1, \dots, N \quad (3)$$

The order statistics obtain from sorting and optionally scaling the data. If the data sample is drawn from the target distribution, a q-q plot will be a straight line, while departures from a line yield insights into their actual distribution. A q-q plot emphasizes the target distribution tails and hence is useful for detecting outliers but is not sensitive near the distribution mode.

Figure 2a shows a q-q plot for 1000 random samples from a standard normal distribution but with the four smallest and largest values replaced by outlying values. The outliers are readily apparent at the bottom and top of the line. The dashed lines show confidence bounds obtained using the $1 - \alpha$ probability value of the Kolmogorov-Smirnov statistic c_α , plotting $F^{*-1}(u)$ against $F^{*-1}(u \mp c_\alpha)$ with $\alpha = 0.05$; see Chave (2017a, §7.2) for further details. Because the confidence bounds flare outward at the distribution extremes, the outliers are not sufficiently large to be quantitatively detected.

The percent-percent or p-p plot also enables the assessment of the distribution of a set of data in a qualitative manner and can be made quantitative by adding error bounds based on the Kolmogorov-Smirnov statistic. A p-p plot consists of the uniform quantiles (3) plotted against the order statistics $x_{(i)}$ of the data sample transformed using a target cdf, typically after standardizing the data. As with a q-q plot, a p-p plot will be a straight line if the target distribution is correct, and deviations from a straight line provide insight into the actual distribution of the data. However, a p-p plot is most sensitive near the

Statistical Computing, Fig. 2 (left) Q-q plot for 1000 random samples from a standard Gaussian distribution with the four smallest and largest values replaced by outliers, along with dashed lines showing the 95% confidence interval on the result. (right) P-p plot for the same data

distribution mode and hence is not very useful for outlier detection but is quite useful for data that are drawn from long-tailed distributions. Michael (1983) introduced a useful variant on the p-p plot that equalizes its variance at all points.

Figure 2b shows a p-p plot of the contaminated Gaussian sample from Fig. 2a. The outliers are barely visible as a slight turn to the left and right at the bottom and top of the line. Confidence bounds are omitted but can easily be added.

The outcome of a statistical procedure may require the identification and elimination of outlying data. This is called censoring and requires changes to both q-q and p-p plots in its presence, as the target distribution has to be truncated. Let $f_x(x)$ and $F_x(x)$ be the pdf and cumulative distribution function (cdf), respectively, of the data before truncation. The pdf of the truncated data set is

$$f'_x(x') = \frac{f_x(x)}{F_x(d) - F_x(c)} \quad (4)$$

where $c \leq x' \leq d$. Suppose the original number of data is N , and the number of data censored at the bottom and top of the distribution are m_1 and m_2 , respectively. Suitable choices for c and d are the m_1 th and $N - m_2$ th quantiles of the original distribution $f_x(x)$. A q-q or p-p plot computed using (4) as the target distribution against the censored data will yield the correct result.

Exploratory data analysis sometimes requires the computation of combinations of distributions or understanding of the properties of specific distributions that cannot be obtained analytically. A suitable substitute is simulation. An example appears in Chave (2014), where it was postulated that the residuals obtained from magnetotelluric (MT) response function estimation are pervasively distributed as a member of the

stable family (a set of distributions characterized by infinite variance and sometimes mean and which describe phenomena in fields ranging from physics to finance). Stable distributions have four parameters (tail thickness α , skewness, location, and scale), and while there are known relationships for the latter three parameters for ensembles of stable random variables, these do not exist for α . Chave (2014) used simulation to show that ensembles of stable random variables with different tail thickness parameters converge to a stable distribution with a new value for α . He did this by obtaining 10,000 random draws from a uniform distribution over the range $[0.6, 2.0]$ to specify α in random draws from a standardized symmetric stable distribution. The ensemble was fit by a stable distribution with a tail thickness parameter of 1.16.

Resampling Methods

Beginning in the early twentieth century, a variety of parametric (meaning that they are based on some distributional assumptions) estimators for the mean and variance (among other statistics) and for hypothesis testing were established. In many instances, a data analyst will not want to make assumptions about the data distribution required for parametric estimators due to the possibility of mixture distribution, outliers, and non-centrality. This led to the development of estimators based on resampling of the data as computational power grew. The most widely used resampling estimator is the bootstrap introduced by Efron (1979). More recently, permutation hypothesis tests that typically are more powerful than the bootstrap have been developed.

The empirical distribution based on the data sample plays a central role in the bootstrap, taking the place of a parametric

sampling distribution. The bootstrap utilizes sampling with replacement (meaning that a given sample may be obtained more than once) and hence is not exact. It can be used for parameter estimation, confidence interval estimation, and hypothesis testing. Suppose that the statistic of interest is $\hat{\lambda}_N$ along with its standard error. Obtain B bootstrap samples $\mathbf{X}_k^*$ from the data set, each of which contains N samples, by resampling with replacement. Apply the estimator for $\hat{\lambda}_N$ to each bootstrap sample to get a set of bootstrap replicates $\hat{\lambda}_N^*(\mathbf{X}_k^*)$ for $k = 1, \dots, B$. The sample mean of the bootstrap replicates is

$$\bar{\lambda}^* = \frac{1}{B} \sum_{k=1}^B \hat{\lambda}_N^*(\mathbf{X}_k^*) \quad (5)$$

and the standard error on $\hat{\lambda}_N$ is

$$SE_B(\hat{\lambda}_N) = \left\{ \frac{1}{B} \sum_{k=1}^B [\hat{\lambda}_N^*(\mathbf{X}_k^*) - \bar{\lambda}^*]^2 \right\}^{1/2} \quad (6)$$

The same methodology applies to other common statistics such as the skewness or kurtosis. While statistical lore holds that a couple of hundred replicates should suffice, it is better to use many thousands and examine the bootstrap distribution for consistency with a given statistic; see Chave (2017a, §8.2) for the details. Note also that a naïve bootstrap applied to estimators derived from the order statistics (e.g., the interquartile range) will fail to converge.

The bootstrap is most commonly used to obtain confidence intervals when the statistic under study is complicated such that its sampling distribution is either unknown or difficult to work with. The standard bootstrap confidence intervals are computed by simply substituting bootstrap estimates for the statistic and its standard deviation into the Student t confidence interval formula, yielding

$$\Pr \left[\bar{\lambda}^* - t_{N-1} \left(1 - \frac{\alpha}{2} \right) SE_B(\hat{\lambda}_N) \leq \lambda \leq \bar{\lambda}^* + t_{N-1} \left(1 - \frac{\alpha}{2} \right) SE_B(\hat{\lambda}_N) \right] = 1 - \alpha \quad (7)$$

where $\bar{\lambda}^*$ and $SE_B(\hat{\lambda}_N)$ are given by (5) and (6).

A better approach to the naïve formulation (7) is the bootstrap-t confidence interval based on the bootstrap replicates given by the normalized statistic:

$$z_k^* = \frac{\hat{\lambda}_N^* - \bar{\lambda}^*}{SE_B(\hat{\lambda}_N)} \quad (8)$$

The $\{z_k^*\}$ are then sorted, and the $\alpha/2$ and $1 - \alpha/2$ values are extracted for use in (7) in place of the t_{N-1} quantile. Accurate

results require the use of a large (many thousands) number of bootstrap replicates. The bootstrap percentile method directly utilizes the $\alpha/2$ and $1 - \alpha/2$ quantiles of the bootstrap distribution and has better convergence and stability properties than either the standard or bootstrap-t approaches.

The best bootstrap confidence interval estimator is the bias-corrected and accelerated (BCa) approach that adjusts the percentile method to correct for bias and skewness. The formulas for bias correction and acceleration are complicated and will be omitted; see Chave (2017a, §8.2.3) for details. It is the preferred approach for most applications.

The bootstrap is also useful for hypothesis testing, although the results typically are neither exact (meaning that the probability of a type 1 error for a composite hypothesis is α for all of the possibilities which make up the hypothesis) nor conservative (meaning that the type 1 error never exceeds α); an exact test is always conservative. A better alternative for most applications is the permutation test that was introduced by Pitman (1937) but only became practical in recent years due to its computational complexity. Permutation tests are usually applied to the comparison of two populations, although they can be used with a single data set with some additional assumptions. A permutation test is at least as powerful as the alternative for large samples and is nearly distribution-free, requiring only very simple assumptions about the population. Permutation tests are based on sampling without replacement. A sufficient condition for a permutation test to be exact and unbiased is exchangeability of the observations (meaning that any finite permutation of their indices does not change their distribution) in a combined sample.

Hypothesis testing usually utilizes the p-value to make decisions. A p-value is the probability of observing a value of the test statistic as large as or larger than the one that is observed for a given experiment. A small number is taken as evidence for the alternate hypothesis or rejection of the null hypothesis. The definition of small is subjective, but typically a p-value below 0.05 is taken as strong evidence for rejection of the null hypothesis. A p-value is a random variable and should not be confused with the type 1 error α which is a parameter chosen before an experiment is performed and hence applies to an ensemble of experiments. The p-value concept is not without controversy, and the American Statistical Association issued a statement on its concept, context, and purpose in Wasserstein and Lazar (2016) that is certainly pertinent.

The key steps in carrying out a permutation test on two populations $\mathbf{X}$ and $\mathbf{Y}$ are:

1. Choose a test statistic $\hat{\lambda}$ that measures the difference between $\mathbf{X}$ and $\mathbf{Y}$.
2. Compute the value of the test statistic for the original sets of data.

3. Combine $\mathbf{X}$ and $\mathbf{Y}$ into a pooled data set.
4. Compute the permutation distribution of $\hat{\lambda}$ by randomly permuting the pooled data, ensuring that the values are unique to enforce sampling without replacement, and recompute the test statistic $\hat{\lambda}_k$.
5. Repeat step 4 many (typically tens of thousands to millions) of time.

6. Accept or reject the null hypothesis according to the p-value for the original test statistic compared with the permutation test statistics.

Let B be the number of permutations. The two-sided equal tail permutation p-value is given by

$$p_{perm} = 2 \times \min \left\{ \frac{1}{B+1} \left[\sum_{i=1}^B \mathbf{1}(\hat{\lambda}_k^* \geq \hat{\lambda}) + 1 \right], \frac{1}{B+1} \left[\sum_{i=1}^B \mathbf{1}(\hat{\lambda}_k^* < \hat{\lambda}) + 1 \right] \right\} \quad (9)$$

where $\mathbf{1}(x)$ is an indicator function that is either 0 or 1 as x is negative or positive. An example taken from Chave (2017a, §8.3.3) serves to illustrate a permutation test. In the 1950s and 1960s, several countries carried out experiments to see if cloud seeding would increase the amount of rain. Simpson et al. (1975) provide an exemplar data set containing 52 clouds, half of which were unseeded or seeded. Q-q plots of the data show that they are quite non-Gaussian, and a q-q plot of the logarithms of the data is quite linear. A two-sample t test on the data yields a p-value of 0.0511, which constitutes weak acceptance of the null hypothesis that unseeded and seeded clouds yield different amounts of rain. However, a two-sample t test on the logs of the data yields a p-value of 0.0141, strongly rejecting the null hypothesis. A permutation test will be used to test the null hypothesis using 1,000,000 permutations of the merged data set. The test statistic is the difference of the means of the first and last 26 entries in the permuted merged data. A set of 1,000,000 random permutations of the 52 data indices is generated and checked to ensure that none of them constitutes the original data order and that they are unique. The p-value (9) is 0.0441, rejecting the null

hypothesis. Repeating the permutation test using the logs of the data gives a p-value of 0.0143, again strongly rejecting the null hypothesis and showing that a permutation test does not require strong distributional assumptions, in contrast to the parametric t test. Figure 3 shows the permutation distribution compared to a Gaussian distribution using sample mean and variance as its parameters for reference and the value of the test statistic.

Permutation tests can be used for one sample tests if the underlying data distribution is symmetric. It can also be applied to two sample tests on paired data such as come from medical trials, where patients are assigned at random to control and treated groups, and two sample tests for dispersion. Care is required in devising a test statistic for the latter unless the means of the two data sets are known to be the same. The solution is to first center each data set about its median value and then use the difference of the sum of squares or absolute values as the test statistic. Details on these applications may be found in Chave (2017a, §8.3).

A final application of resampling is bias correction in goodness-of-fit tests such as the Kolmogorov-Smirnov or Anderson-Darling types. It is well known that such tests require that the parameters in the target distribution be known a priori, a condition that rarely holds in practice, and they are usually estimated from the data. This results in unknown bias in the test which can be removed using a Monte Carlo approach. The steps to follow are:

1. Obtain the test statistic for the N observations against a target distribution whose parameters are estimated from the data.
2. Compute N random draws with replacement from the target distribution using the same parameters.
3. Obtain the K-S or A-D statistic for the random draw.
4. Repeat steps 2 and 3 a large number of times.
5. Compute the p-value using (9).

Statistical Computing, Fig. 3 Kernel density pdf of the distribution of the test statistic for the cloud seeding data. The vertical dashed line is the test statistic based on all of the data. (Taken from Chave (2017a))

This approach was used by Chave (2017b) to remove bias while assessing the fit of a stable distribution to regression

residuals in the computation of the magnetotelluric response function.

Linear Regression

Linear regression is the most widely used statistical procedure in existence. It encompasses problems that can be cast as a linear model for p parameters given N data, where $p \leq N$ is assumed

$$\mathbf{y} = \leftrightarrow \mathbf{X} \cdot \boldsymbol{\beta} + \boldsymbol{\epsilon} \quad (10)$$

where $\mathbf{y}$ is the response N -vector, $\leftrightarrow \mathbf{X}$ is an $N \times p$ matrix of predictors, $\cdot$ denotes the inner product, $\boldsymbol{\beta}$ is a parameter p -vector, and $\boldsymbol{\epsilon}$ is an N -vector of unobservable random errors. Four assumptions underlie linear regression: (a) the model is linear in the parameters, which is implied by (10); (b) the error structure is additive, which is also implied by (10); (c) the random errors have zero mean and equal variance while being mutually uncorrelated; and (d) the rank of the predictor matrix is p .

In elementary statistical texts, the predictor variables are presumed to have no measurement error, which is rarely true in practice. In real applications, $\leftrightarrow \mathbf{X}$ contains random variables, in which case the statistical model underlying (10) is

$$\begin{aligned} E(\mathbf{y} | \leftrightarrow \mathbf{X}) &= \leftrightarrow \mathbf{X} \cdot \boldsymbol{\beta} \\ \text{cov}(\mathbf{y} | \leftrightarrow \mathbf{X}) &= \sigma^2 \leftrightarrow \mathbf{I}_N \end{aligned} \quad (11)$$

where the leading elements are the conditional expected value and covariance, σ^2 is the population variance, and $\leftrightarrow \mathbf{I}_N$ is the $N \times N$ identity matrix. The least squares estimator for (10) is

$$\hat{\boldsymbol{\beta}} = (\leftrightarrow \mathbf{X}^H \cdot \leftrightarrow \mathbf{X})^{-1} \cdot \leftrightarrow \mathbf{X}^H \cdot \mathbf{y} \quad (12)$$

where the superscript H denotes the Hermitian transpose to accommodate complex response and predictor variables.

A list of the properties of the linear regression estimator is given in Chave (2017a, §9.2). A summary is:

1. The unconditional expected value of (12) is

$$E(\hat{\boldsymbol{\beta}}) = \boldsymbol{\beta} \quad (13)$$

so that linear regression is unbiased presuming assumption (c) holds.

2. The unconditional covariance matrix for $\hat{\boldsymbol{\beta}}$ is

$$\text{cov}(\hat{\boldsymbol{\beta}}) = \sigma^2 E((\leftrightarrow \mathbf{X}^H \cdot \leftrightarrow \mathbf{X})^{-1}) \quad (14)$$

and in practice the expected value is replaced with an estimate.

3. The predicted value N -vector is

$$\hat{\mathbf{y}} = \leftrightarrow \mathbf{X} \cdot (\leftrightarrow \mathbf{X}^H \cdot \leftrightarrow \mathbf{X})^{-1} \cdot \leftrightarrow \mathbf{X}^H \cdot \mathbf{y} \equiv \leftrightarrow \mathbf{H} \cdot \mathbf{y} \quad (15)$$

where $\leftrightarrow \mathbf{H}$ is the $N \times N$ hat matrix. The hat matrix is a projection matrix and hence is symmetric and idempotent. Its diagonal elements $\hat{h}_{ii}$ are real and satisfy $0 \leq \hat{h}_{ii} \leq 1$. Chave and Thomson (2003) showed that when the rows of $\leftrightarrow \mathbf{X}$ are complex multivariate Gaussian, the distribution of $\hat{h}_{ii}$ is beta with parameters p and $N - p$.

4. The estimated regression residuals are given by

$$\hat{\mathbf{r}} = \mathbf{y} - \leftrightarrow \mathbf{X} \cdot \hat{\boldsymbol{\beta}} = (\leftrightarrow \mathbf{I}_N - \leftrightarrow \mathbf{H}) \cdot \mathbf{y} \quad (16)$$

5. The sum of squared residuals is

$$\hat{\mathbf{r}}^H \cdot \hat{\mathbf{r}} = \mathbf{y}^H \cdot (\leftrightarrow \mathbf{I}_N - \leftrightarrow \mathbf{H}) \cdot \mathbf{y} \quad (17)$$

6. An unbiased estimate for the variance is

$$\hat{\sigma}^2 = \frac{\hat{\mathbf{r}}^H \cdot \hat{\mathbf{r}}}{N - p} \quad (18)$$

7. The regression residuals $\hat{\mathbf{r}}$ are uncorrelated with the predicted values $\hat{\mathbf{y}}$.
8. The parameter vector $\hat{\boldsymbol{\beta}}$ is the best linear unbiased estimator (Gauss-Markov theorem).
9. Statements 1–8 do not require any distributional assumptions. If the random errors are real and N -variate Gaussian distributed with mean μ and common variance σ^2 , then $\hat{\boldsymbol{\beta}}$ is also the maximum likelihood estimator and hence $(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}) / \hat{\sigma}$ converges in distribution to a standardized Gaussian distribution. Further,

$$\begin{aligned} \hat{\boldsymbol{\beta}} &\sim N_p(\boldsymbol{\beta}, \sigma^2 (\leftrightarrow \mathbf{X}^H \cdot \leftrightarrow \mathbf{X})^{-1}) \\ \frac{(N - p) \hat{\sigma}^2}{\sigma^2} &\sim \chi_{N-p}^2 \end{aligned} \quad (19)$$

where $\sim$ means “is distributed as” and N_p is a p -variate Gaussian. In addition, the regression estimator is consistent, and $\hat{\boldsymbol{\beta}}$ and $\hat{\sigma}^2$ are independent and serve as sufficient statistics for estimating $\boldsymbol{\beta}$ and σ^2 . Complex random errors require that propriety also be considered; see Schreier and Scharf (2010) for the details.

Equation (12) is called the normal equation solution and possesses poor numerical properties, particularly when the

predictor matrix has entries that cover a wide range. The problem comes from inverting $\leftrightarrow \mathbf{X}^H \cdot \leftrightarrow \mathbf{X}$, and the issue can be avoided if that step is removed. The predictor matrix can always be factored into the product of two matrices $\leftrightarrow \mathbf{Q} \cdot \leftrightarrow \mathbf{R}$, where $\leftrightarrow \mathbf{Q}$ is $N \times p$ orthonormal, so that $\leftrightarrow \mathbf{Q}^H \cdot \leftrightarrow \mathbf{Q} = \leftrightarrow \mathbf{I}_p$. The second matrix is $p \times p$ upper triangular, so that all of the entries to the left of the main diagonal are zero. Combining the QR decomposition with the least squares problem yields

$$\mathbf{Q}^H \cdot \mathbf{y} = \leftrightarrow \mathbf{R} \cdot \hat{\boldsymbol{\beta}} \quad (20)$$

The left side of (19) is a p -vector. The p -th row of $\hat{\boldsymbol{\beta}}$ multiplied by the (p, p) element of $\leftrightarrow \mathbf{R}$ is equal to the p th element of the left side of (20). Stepping up one row, there is only one unknown because the p -th element of $\hat{\boldsymbol{\beta}}$ is already determined. This process of stepping back row by row is called back substitution, and the least squares problem has been solved without ever computing $\leftrightarrow \mathbf{X}^H \cdot \leftrightarrow \mathbf{X}$ or its inverse. QR decomposition is the best approach for numerically solving least squares problems.

Statistical inference for linear regression comprises a set of tools for assessing the fit of a given set of data to a linear model. Analysis of variance (ANOVA) provides a gross tool to assess the need for linear regression and, along with the widely used residual sum of squares, is not very informative. A more useful approach is a test of the null hypothesis $H_0 : \hat{\beta}_j = \beta_j^*$ against the alternate hypothesis $H_1 : \hat{\beta}_j \neq \beta_j^*$, where β_j^* is a particular value for the j th element in $\boldsymbol{\beta}$. The most widely used case sets $\beta_j^* = 0$ to test whether a given parameter is required. Let $\hat{\boldsymbol{\zeta}} = \leftrightarrow \mathbf{X}^H \cdot \leftrightarrow \mathbf{X}$. The test statistic is

$$\hat{t}_j = \frac{\sqrt{\hat{\zeta}_{jj}}(\hat{\beta}_j - \beta_j^*)}{\hat{\sigma}} \quad (21)$$

and is distributed as Student's t distribution with $N - p$ degrees of freedom if the null hypothesis is true. It is standard practice to produce a table that lists each element in $\boldsymbol{\beta}$, its standard error, the test statistic (21), and the corresponding p -value. If a given element of $\boldsymbol{\beta}$ has a p -value that lies below the type 1 error level α , then it should be removed from the linear model, although this must be done carefully and in conjunction with assessing the regression for outlying data.

The well-known equivalence between hypothesis testing and confidence interval estimation yields that the $1 - \alpha$ confidence interval on $\hat{\beta}_j$ is the set of all values for β_j^* for which the null hypothesis is acceptable with a type 1 error of α . Consequently, it follows that the $1 - \alpha$ confidence interval on β_j is

$$\begin{aligned} \hat{\beta}_j - t_{N-p} \left(1 - \frac{\alpha}{2}\right) \sqrt{\frac{\hat{\mathbf{r}}^H \cdot \hat{\mathbf{r}}}{[(N-p)\hat{\zeta}_{jj}]} } &\leq \beta_j \\ &\leq \hat{\beta}_j + t_{N-p} \left(1 - \frac{\alpha}{2}\right) \sqrt{\frac{\hat{\mathbf{r}}^H \cdot \hat{\mathbf{r}}}{[(N-p)\hat{\zeta}_{jj}]} } \end{aligned} \quad (22)$$

When there is more than one parameter in $\boldsymbol{\zeta}$, the Bonferroni method of replacing α with α/p should be utilized to avoid underestimating the confidence interval.

The bootstrap may also be used to estimate both the regression parameters and confidence intervals on them and is preferred because it does not depend as strongly on distributional assumptions compared to the parametric form (22). First, B bootstrap replicates are obtained by sampling with replacement from the response and predictor variables, and the linear regression estimator is applied to each to yield the $B \times p$ matrix $\{\hat{\boldsymbol{\beta}}_k^*\}$ whose column averages are the bootstrap estimate of the regression coefficients $\bar{\boldsymbol{\beta}}^*$. Bootstrap confidence intervals using the percentile method follow by sorting the columns of $\hat{\boldsymbol{\beta}}_k^*$ and taking the $[Ba/2p]$ and $[B(1 - \alpha)/2p]$ entries as the confidence interval for each. The BCa method may also be utilized. A double bootstrap estimator may be used to assess the significance of the regression coefficients; see Chave (2017), §9.4.3, and §9.5.2 for the details.

It is important to evaluate the regression residuals for lack of correlation, or randomness, to see that assumption (c) above is in effect. This is most easily achieved using the nonparametric Wald-Wolfowitz runs test that is described in Kvam and Vidakovic (2007) §6.5. The regression residuals should also be evaluated for the presence of autocorrelation using the Durbin-Watson test. Positive autocorrelation in the residuals will downward bias the parameter standard errors, hence increasing the false rejection rate on the parameters themselves. The details may be found in Chave (2017a) §9.4.4.

Influential data are those that are statistically unusual or that exert undue control on the outcome of a linear regression. They are classified as outliers or leverage points when they appear in the residuals and predictors, for which the hat matrix diagonal is a useful statistic. It is certainly possible to hand cull these from small data sets, but as data sets get larger this becomes impractical. What is needed is estimators that are robust to outlying data but that approach the efficiency of standard linear regression when outliers are absent. Such estimators have been devised over the past 50 years. The most widely used robust estimators are maximum-likelihood-like, or M-estimators. Chave et al. (1987) review the topic in a geophysical context.

M-estimators turn maximum likelihood estimation backward by a priori specifying a loss function that ensures robustness while maintaining efficiency rather than

specifying their distribution. The loss function $\rho(r)$ for a Gaussian distribution is $r^2 + c$, where c is a constant and r is a residual (e.g., difference between a datum x_i and the mean λ), and the estimation problem is

$$\min_{\lambda} \sum_{i=1}^N \rho(r_i) \quad (23)$$

A typical M-estimator will utilize a loss function that is Gaussian at the center but with longer tails at the extremes.

Taking the derivative in (23) with respect to λ yields the M-estimation analog to the normal equations:

$$\sum_{i=1}^N \psi(r_i) = 0 \quad (24)$$

where $\psi(r) = \partial_r \rho(r)$, and $\psi(r)$ is called the influence function.

Huber (1964) introduced a simple robust estimator based conceptually on a model that is Gaussian at the center and double exponential in the tails. The double exponential is the natural distribution for the L1 (least absolute values) norm, just as the Gaussian is the natural estimator for the L2 (least squares) norm. The loss and influence functions for the Huber estimator are

$$\begin{aligned} \rho(r) &= r^2 \quad |r| \leq \alpha \\ &= \alpha|r| - \frac{\alpha^2}{2} \quad |r| > \alpha. \\ \psi(r) &= r \quad |r| \leq \alpha \\ &= \alpha \operatorname{sgn}(r) \quad |r| > \alpha \end{aligned} \quad (25)$$

When $\alpha = 1.5$, the Huber estimator has 95% efficiency with purely Gaussian data, in contrast with an L1 estimator that has a ~60% variance penalty. From (25), the Huber estimator clearly bounds the influence of extreme data where the L2 estimator does not. More extreme loss and influence functions may be devised; for example, trimming the data at $|r| = \alpha$ means replacing the second terms in (25) with $\alpha^2/2$ and 0, respectively.

The numerical implementation of a robust estimator requires two additional steps because (24) is nonlinear, as the residuals are not known until the equation is solved. The argument in (23) or (24) must be independent of the scale of the data; in the Huber estimator (25), the L2 to L1 transition occurs at $\alpha = 1.5$ standard deviations, so the argument needs to be expressed in standard deviation rather than data units. This can be achieved by replacing r_i in (24) with r_i/d , where d is the sample scale estimate divided by the population scale estimate for the target distribution (which is usually Gaussian). The parameter d should not be sensitive to extreme data;

a suitable choice is s_{IQ}/σ_{IQ} , where IQ means the interquartile range.

The second step in implementing a robust estimator is linearization of the equations. This is accomplished by rewriting (24) as a weighted least squares problem:

$$\begin{aligned} \sum_{i=1}^N \psi(r_i) &\approx \sum_{i=1}^N w_i r_i = 0 \\ w_i &= \frac{\psi(r_i/d)}{r_i/d} \end{aligned} \quad (26)$$

Linearization is achieved by iteratively solving (26) and computing the weights w_i and scale d using the residuals r_i from the prior iteration. Equation (26) is initialized using standard least squares (i.e., $w_i = 1$), and the iterative solution proceeds until the sum of squared residuals does not change above a threshold amount (such as 1%).

The robust estimator extends to linear regression if the residuals in (24) are identified as the regression residuals (15). Performing the minimization that yielded (24) gives

$$\sum_{i=1}^N \psi(r_i/d) x_{ij} = 0 \quad (27)$$

whose solution using weighted least squares is straightforward. The result should be assessed using the runs test, Durbin-Watson test, and t-statistic p-value, along with a q-q plot to check for outliers, just as for ordinary linear regression.

Rousseeuw and Leroy (1987, p. 27) presented what is now a classic data set comprising the logarithms of the effective surface temperature and light intensity of stars from the cluster Cygnus OB1. Chave (2017a) §9.5.2 presented their analysis including an intercept using tedious manual culling that showed that four outlying values due to red giant stars were “pulling” the fit and yielding a result that is orthogonal to the visual best fit. In §9.6.1, Chave (2017a) repeated the analysis using a Huber robust estimator. Only one iteration ensued, and the normalized sum of squared residuals was reduced from 0.3052 to 0.3049. The residuals are random and uncorrelated, but the regression is not fitting anything very well. Figure 4 shows the data and the fitted line. It is clear that the four red giant stars at the upper left are “pulling” the fit and forcing it to be rotated about 90° from a visual best fit through the main cluster of stars at the right side of the plot. In fact, the robust fit is not very different from what is achieved with ordinary least squares. The problem is that the red giant stars produce leverage manifest in the predictors rather than outliers manifest in the residuals, and robust estimators are insensitive to leverage points. In fact, M-estimators often make leverage worse or create leverage points that were not present at the start.

Statistical Computing, Fig. 4 The star data (crosses) along with a robust linear regression fit including an intercept (dashed)

This limitation has led to the introduction of bounded influence estimators that protect against both outliers and leverage points. Chave and Thomson (2003) replaced (26)–(27) with

$$\sum_{i=1}^N w_i^{[k]} v_i^{[k]} r_i^{[k-1]} x_{ij} = 0 \quad j = 1, \dots, p \quad (28)$$

where the superscript in brackets denotes the iteration number. The first set of weights w_i are standard M-estimator weights such as the Huber set. The second set of weights v_i utilize a hat matrix measure of leverage that is applied in an iteratively multiplicative fashion to prevent instability as leverage points appear and disappear during the solution of (28). The form used is

$$v_i^{[k]} = v_i^{[k-1]} \exp\left(-e^{\chi(x_i - \chi)}\right) \quad (29)$$

The statistic x_i is chosen to be $Nh_{ii}^{[k]}/p$, where $h_{ii}^{[k]}$ is the diagonal elements of the hat matrix that includes the product of the M-estimator and leverage weights. The free parameter χ sets the value where down-weighting begins, and a suitable

value is the Nth quantile of the beta distribution with parameters $(p, N - p)$ at some chosen probability level, such as 0.99.

Returning to the star data, the bounded influence estimator (28) was applied, resulting in four iterations during which the normalized residual sum of squares was reduced from 0.3052 to 0.1140. The residuals are random and uncorrelated. Weighted residual and hat matrix diagonal qq-plots reveal no outliers or leverage points remaining, and five data have been removed by the estimator. Figure 5 shows the result, which compares favorably with the hand-culled result from Chave (2017a) §9.5.2.

Nonlinear Multivariable Maximum Likelihood Estimation

As a final example of statistical computing, the implementation of a maximum likelihood estimator (MLE) for the analysis of magnetotelluric (MT) data will be described. MT utilizes measurements of the electric and magnetic fields on Earth's surface to infer the electrical structure beneath it. The fundamental datum in MT is a location-specific, frequency-

Statistical Computing, Fig. 5 The star data (crosses) and a bounded influence linear regression fit to them including an intercept (dashed).

The axis limits are the same as for Fig. 4, and data that have been eliminated by bounded influence weighting have been omitted

dependent tensor $\leftrightarrow \mathbf{Z}$ linearly connecting the horizontal electric and magnetic fields $\mathbf{E} = \leftrightarrow \mathbf{Z} \cdot \mathbf{B}$. This relation does not hold exactly when $\mathbf{E}$ and $\mathbf{B}$ are measurements, and instead the row-by-row linear regression is employed:

$$\mathbf{e} = \leftrightarrow \mathbf{b} \cdot \mathbf{z} + \boldsymbol{\epsilon} \quad (30)$$

where $\mathbf{e}$ is the electric field response N -vector, $\leftrightarrow \mathbf{b}$ is the $N \times 2$ magnetic field predictor matrix, $\mathbf{z}$ is the MT response 2-vector, and $\boldsymbol{\epsilon}$ is an N -vector of random errors, with all of these entities being complex. The time series measurements are Fourier transformed into the frequency domain over N segments that are of order one over the frequency of interest in length; see Chave (2017b) for details.

MT was plagued by problems with bias and erratic responses until the late 1980s, when robust and then bounded influence estimators were devised that dramatically improved results. All of these approaches are based on the robust model comprising a Gaussian core of data plus outlying non-Gaussian data that cause analysis problems. However, Chave (2014, 2017b) showed that the residuals from a robust estimator were systematically long tailed, so that the Gaussian core does not exist, and then showed that the residuals were

pervasively distributed according to a stable model. This immediately suggested that an MLE based on the stable model could be implemented.

For stable MT data, the pdf of a single residual is $S(\hat{r}_i|\boldsymbol{s})$, where $\hat{r}_i = e_i - \mathbf{b}_i \cdot \hat{\mathbf{z}}$ is the i th estimated residual, $\mathbf{b}_i$ is the i th row of $\leftrightarrow \mathbf{b}$ in (30), and $\boldsymbol{s} = (\alpha, \beta, \gamma, \delta)$ are the tail thickness, skewness, scale, and location parameters for a stable distribution. For independent data, the sampling distribution is

$$S_N(\hat{\mathbf{r}}|\boldsymbol{s}) = \prod_{i=1}^N S(\hat{r}_i|\boldsymbol{s}) \quad (31)$$

The likelihood function is the sampling distribution regarded as a function of the parameters for a given set of residuals. The MLE is obtained by maximizing the likelihood function, or equivalently its logarithm:

$$L(\boldsymbol{s}, \mathbf{z}|\hat{\mathbf{r}}) = \sum_{i=1}^N \log S(\hat{r}_i|\boldsymbol{s}) \quad (32)$$

The first-order conditions for the MLE solution follow by setting the derivatives of (32) with respect to the parameters to zero:

Statistical Computing,

Fig. 6 The real and imaginary parts of the Z_{xy} component of the MT response scaled by the square root of period for a site located in South Africa. The confidence limits for the robust (gray) and stable MLE (black) are obtained using the jackknife and diagonal elements of the improper Fisher information matrix, respectively, assuming that the tail probability is apportioned equally among the eight real and imaginary elements of the response tensor. The stable MLE estimates have been offset slightly for clarity. (Taken from Chave (2014))

$$\partial_{\hat{r}_j} L(\mathbf{s}, \mathbf{z} | \hat{\mathbf{r}}) = \sum_{i=1}^N \frac{\partial_{\hat{r}_j} S(\hat{\mathbf{r}}_i | \mathbf{s})}{S(\hat{\mathbf{r}}_i | \mathbf{s})} = 0 \quad j = 1, \dots, 4$$

$$\partial_{z_k} L(\mathbf{s}, \mathbf{z} | \hat{\mathbf{r}}) = \sum_{i=1}^N \frac{\partial_{z_k} S(\hat{\mathbf{r}}_i | \mathbf{s})}{S(\hat{\mathbf{r}}_i | \mathbf{s})} b_{ik} = 0 \quad k = 1, \dots, 4 \quad (33)$$

The sufficient condition for the solution to (33) to be a maximum is that the Hessian matrix of the log likelihood function (32) be negative definite.

Chave (2014) solved (33) using a two-stage approach that decouples the stable distribution parameter vector $\mathbf{s}$ and the MT response function $\mathbf{z}$. In the first stage, the stable distribution was estimated using the stable MLE algorithm of Nolan (2001). In the second stage, the MT response function was obtained using the second part of (33) while fixing the stable distribution parameters. This proceeds iteratively until convergence is obtained. The starting solution is the ordinary least squares result with 5% trimming.

Equations (31) can be solved using a weighted least squares approach, but convergence slows as the tail thickness parameter α decreases toward 1 and fails for smaller values. Experience showed that MT data exhibit tail thicknesses as low as 0.8, so this limitation was a real problem. An alternative approach utilized nonlinear multivariable minimization of an objective function based on a trust region algorithm for the second stage, including explicit provision of the gradient and Hessian matrix to speed convergence. The objective function that was minimized is the negative log likelihood given by (32) preceded by a minus sign and with the stable parameter vector fixed. This method worked well for all values of the tail thickness parameter at the cost of one to two orders of magnitude more computer time than weighted least squares.

Figure 6 shows a typical result from the stable MLE compared to a standard robust estimator. The stable MLE produces a smoother result as a function of frequency, as

expected from diffusion physics, and smaller error estimates as compared to a bounded influence estimator. The latter is because the MLE is asymptotically efficient, reaching the lower bound of the Cramér-Rao inequality which a bounded influence estimator cannot achieve. In fact, there are substantial differences (up to 10 standard deviations) between the stable MLE and bounded influence results, although these are subtle in Fig. 6. The tail thickness parameter hovers around 1 at periods under 30 s. The p-values for a test of the null hypothesis that the data are stably distributed based on the Kolmogorov-Smirnov statistic does not reject at any frequency once the test is corrected for bias due to estimation of the distribution parameters from the data using the resampling approach described above.

Summary

This chapter has covered four topics in statistical computing: exploratory data analysis, resampling methods, linear regression, and nonlinear optimization. The first topic includes tools to statistically characterize a data set using a kernel density estimator, quantile-quantile plot, percentile-percentile plot, and simulation. Resampling methods include the use of the bootstrap to compute estimators and confidence limits and permutation methods for hypothesis testing that are nearly exact. Linear regression was described both theoretically and numerically and then extended to robust and bounded influence estimators that automatically handle unusual data (e.g., outliers). Nonlinear optimization was described based on the solution for the magnetotelluric response function after recognizing that such data in the frequency domain pervasively follow a stable distribution. This set of topics is not comprehensive, and many additional ones exist that comprise statistical computing.

Statistical Inferential Testing

R. Webster

Rothamsted Research, Harpenden, UK

Definition

Information on the constituents of rock, sediment, and soil necessarily derive from samples; it is never complete. Inferences drawn from data are uncertain, and the main aim of statistical testing is to attach probabilities to those inferences. The tests are prefaced by hypotheses or models, such as no differences among population means or relations between variables, the so-called null hypotheses. They are designed to refute those hypotheses by determining the probabilities that the hypotheses or models are true, given the data. A result is declared statistically significant when the probability, P , is less than some small value, conventionally $P < 0.05$. Statistical significance is not the same as scientific significance, and calculated values of P should always be presented along with standard errors in reports and papers so that clients and readers can draw their own inferences from results.

Introduction

Statistical inference is a broad subject. In the geosciences it can be narrowed to inferences about *populations* that may be drawn from *sample* data. Rock formations and sediments are continuous bodies of variable material. Soil mantles the land surface except where it is broken by rock, and it too varies both from place to place and from time to time. Knowledge about many of the properties of these materials is incomplete because it derives from observations on samples; one cannot measure them everywhere. Further, measurements themselves are more or less in error. Knowledge of the true states of the materials is therefore uncertain, and one of the main aims of statistics in this context is to put that uncertainty on a quantitative footing; it is to attach probabilities to the inferences drawn from data. Following from it is the notion of statistical significance, of separating meaningful information, i.e., signal, from “noise,” i.e. from unaccountable variation in data or from sources of no interest. The information might be change of some property of the soil arising from change of use, the difference between analyses of the metal content of an ore from two laboratories, and the response of some treatment to combat pollution in a sediment. Given the uncertainties in data, the question then becomes: are observed differences or response so large in relation to the unaccountable variation

that their occurrence by chance is highly improbable? If the answer is “yes,” then the result is said to be “significant”; it will be accompanied by a value P , a measure of this improbability – see below.

A significance test is prefaced by a hypothesis. In the above examples this would be that there has been no effect on the soil caused by change of land use, that results from different laboratories do not differ, that the pollution in the sediment has not abated in response to the treatment. That is the “null hypothesis,” often designated H_0 , and the test is designed to reject it, *not to confirm it*. The alternative that there is a difference is denoted either H_1 or H_A .

A valid test requires (a) a plausible underlying model of the phenomenon being investigated and (b) that the sampling has been suitably randomized to provide the data. Embodied in the model is a statistical distribution within which to judge the data.

The Normal Distribution

Statistical tests of significance are set against a background of variation with assumed probability distributions, by far the commonest of which is the normal, or Gaussian, distribution. Its probability density is given by

$$y = \frac{1}{\sigma\sqrt{2\pi}} \exp\left\{-\frac{(x-\mu)^2}{2\sigma^2}\right\} \quad (1)$$

where μ is the mean and σ^2 is the variance of the distribution. Its graph of y against x is a familiar bell-shaped curve. A variable with mean $\mu = 0$, variance $\sigma^2 = 1$, and this distribution is a standard normal deviate, often denoted z . Many variables describing the properties of geological bodies and materials are distributed approximately in this way or can be made so by transformation of their scales of measurement. Further, the distributions of sample means increasingly approach normal as the sample sizes increase whatever the distributions of individual measurements, a result known as the central limit theorem.

Tests With z

One use of z is to place confidence limits about a population mean, μ , estimated by the mean, $\bar{x}$, of a sample. For a sample of size n with variance s^2 , the variance of its mean is s^2/n and its square root is the standard error. In these circumstances the lower and upper limits on μ for some given confidence are

$$\bar{x} - z\sqrt{s^2/n} \text{ and } \bar{x} + z\sqrt{s^2/n}.$$

Frequently used values are

Confidence(%)	80	90	95	99
z	1.28	1.64	1.96	2.58

The z test is often used to decide whether a sample belongs to some population or that it deviates from some norm with mean μ and variance σ^2 . The null hypothesis is no deviation: $\bar{x} = \mu$. The test is given by

$$z = \frac{\bar{x} - \mu}{\sqrt{\sigma^2/n}}, \quad (2)$$

for which the corresponding probability, P , can be calculated or found in tables of the standard normal deviate for the number of degrees of freedom.

In practice the population variance is rarely known and is estimated by the sample variance, s^2 . In these circumstances, unless the sample is large ($n > \approx 60$), z must be replaced by student's t :

$$t = \frac{\bar{x} - \mu}{\sqrt{s^2/n}}. \quad (3)$$

Again, the values of P corresponding to those of t for the number of degrees are tabulated in published tables and nowadays can be calculated in most statistical packages. For sample sizes exceeding, the distributions of z and t are so similar that the tests give almost identical results.

Equations (2) and (3) lead to probabilities that the differences between $\bar{x}$ and μ lie in either tail of the distributions; the differences may be either negative or positive. The tests are two-tailed or two-sided in the jargon. In many instances investigators are interested in only one tail. For example, a public health authority may want to know only whether the lead content of the soil exceeds some threshold; it would calculate

$$c = \bar{x} - z\sqrt{\sigma^2/n} \text{ or } c = \bar{x} + t\sqrt{\sigma^2/n}, \quad (4)$$

and obtain the corresponding probability, P , which would be half that for the two-sided test.

The F Test

The quantity F , named in honor of R.A. Fisher, is the quotient resulting from the division of one variance, say s_1^2 , by a smaller one s_2^2 : s_1^2/s_2^2 . Fisher worked out its distribution if s_1^2 and s_2^2 are variances of two independent random samples from two normally distributed populations with the same variance σ^2 . The calculated value of F is compared with that distribution to obtain the probability, P , given the evidence, that the null hypothesis, i.e., no difference between the

variances of the populations from which the samples were drawn, is true. The larger is the calculated F , the smaller is P , other things being equal.

More often F is invoked to test for differences among means of classes in experiments and surveys after analyses of variance (ANOVAs). Table 1 is an example; it summarizes the ANOVA of lead (Pb) in the soil in the Swiss Jura classified by geology (from Atteia et al. 1994) with measurements in mg kg⁻¹ transformed to their common logarithms. The probability of $F = 5.95$ under the null hypothesis of no differences among the means is $P < 0.001$; the null hypothesis is clearly untenable. Table 2 reveals why; the soil on the Argovian rocks is poorer in Pb than on the others.

Table 2 lists the means of both the measurements in mg kg⁻¹ and of their transforms to common logarithms to bring the distributions close to normal. The last column lists the standard errors derived from the residual mean square from the ANOVA set out in Table 1. The differences are not huge but with so many data the test is very sensitive.

The natural scientist might seek reasons for the soil on the Argovian's being poorer in Pb. The environmental protection agency might be more concerned because the concentrations of Pb on four of the five formations exceed the statutory limit of 50 mg kg⁻¹.

Individual means may be compared. The standard error of a difference is

$$\text{SED} = \sqrt{\frac{s^2}{n_1} + \frac{s^2}{n_2}}, \quad (5)$$

where s^2 is the residual mean square from the ANOVA and n_1 and n_2 are the sizes of the two samples. Student's t for the comparison of the means, say $\bar{x}_1$ and $\bar{x}_2$, is then

$$t = (\bar{x}_1 - \bar{x}_2) / \text{SED} \quad (6)$$

In this example, the comparison of the Argovian with the four others would be the main interest. It would require a vector of weighting coefficients $\mathbf{w} = \{1, -\frac{1}{4}, -\frac{1}{4}, -\frac{1}{4}, -\frac{1}{4}\}$ by which to multiply both the means and standard errors to obtain the appropriate value of t . Details are set out in Sokal and Rohlf (2012), which is among the most up-to-date and nearly comprehensive didactic texts.

The practice of comparing every pair or sets of pairs in this way is to be deprecated. In particular, one cannot assign a probability to a difference only when it becomes apparent from an ANOVA. Hypotheses should be set out first, and experiments and surveys designed to test them. Ideally, they should comprise orthogonal contrasts, the number of which is equal to the degrees of freedom between classes; Sokal and Rohlf (2012) and Webster and Lark (2018) explain.

If there are only two classes, then the F test is equivalent to the t test: $F = t^2$.

Tests for Normality

Geoscientists often worry that the validity of ANOVAs and regression analyses are compromised if data are not normally distributed. The tests such as the Kolmogorov–Smirnov test, the Shapiro–Wilk test, or a χ^2 test on frequencies of a histogram are of little help. With many data almost any departure from normal will be judged significant, whereas with few data the tests are inconclusive. The tests do not reveal in what way the distributions deviate from normal. Further, what matter for ANOVA and regression are the distributions of the residuals, not those of the data. Far better guides are histograms and Q–Q graphs of the residuals (see Welham et al. 2015). Figure 1 shows the distributions of the residuals from the ANOVAS of the lead data both on the original measurements, Fig. 1a and b, and on their logarithmic transforms, Figure 1c and d, summarized in Table 2. The histogram of the residuals from the

Statistical Inferential Testing, Fig. 1 Histograms and Q-Q graphs of residuals from the analysis of variance of the lead in the soil of the Swiss Jura; (a) and (b) of the original measurements in mg kg^{-1} and (c) and (d)

on their logarithmic transforms. The curve in (c) is that of a normal distribution fitted to the data

ANOVA of the original measurements shows that they are far from normal, and the points on the Q-Q graph form a strong curve. Those of the transformed data are closer to normal, though still somewhat skewed (skewness coefficient 1.22 and points on the Q-Q graph not quite lying on straight line) (Fig. 1c and d). The ANOVA for comparing means is robust against small departures from normality, and it can be used with confidence in such circumstances.

Significance and *P* Value

A *P* value from a statistical test is the probability that the specified statistical model or hypothesis can be held as true in the light of the data. The smaller is this value of *P*, the stronger is the evidence against the model or hypothesis. It is this evidence that constitutes statistical significance, and *P* is its measure. R.A. Fisher originally suggested that a $P \leq 0.05$ was reasonable grounds for rejecting a null hypothesis, for

example, no differences among means, and declaring significance. It has subsequently become a convention. Such has been the misunderstanding and abuse of this threshold that the American Statistical Association felt bound to issue a statement on the matter (Wasserstein and Lazar 2016). The statement comprised six principles summarized below:

1. The first principle reads “*P*-values can indicate how incompatible are the data with a specified statistical model.” Usually the model is a null hypothesis, for example, no differences among means or responses to treatments, and *P* is a measure of the probability that the hypothesis is true.
2. A *P* value *does not* measure the probability that a proposed null hypothesis is true or that the data arose purely at random.
3. Scientific conclusions, business decisions, or policy for action should not be based on *P* values alone.
4. Proper inference requires full reporting and transparency. The concern here is the selection of results with small *P* values that will lead to publications in the scientific literature, a practice known as “*P* hacking.”
5. A *P* value or its equivalent statistical significance does not measure the size of an effect or the importance of a result. Statistical significance is not the same as scientific or practical significance.
6. By itself, a *P* value is not a good measure of evidence regarding a model or hypothesis. A result, small value of *P*, might be statistically significant because with many data the test is very sensitive but of no scientific significance. A nonsignificant result, large *P*, might mean that the null hypothesis is correct, but it does not measure the probability that it is so; a wise scientist takes the view that there is too little evidence to conclude that observed differences apply to the populations from which the samples are drawn.

One can still draw mistaken conclusions as the result of significance test.

Mistakes can be of two kinds, denoted Type I and Type II. The first occurs when one rejects the null hypothesis on the basis of sample evidence, i.e., declares differences significant, when the populations do not differ. The second is when one accepts the null hypothesis, i.e., states that there is insufficient evidence for differences, when the populations do differ. One must realize that $P = 0.05$ is not a dividing line between falsehood and truth. Rather a *P* value lies on a continuous scale from more to less probable. Probabilities can now be readily computed in modern statistical packages; they should be included in all reports of statistical analyses as recommended by Wasserstein and Lazar (2016). If they are published along with the means and their standard errors, then readers can reach their own inferences.

Summary

Geoscientists who want to draw conclusions about populations of rock, sediments, or soil from sample data must contend with uncertainty. Statistical inference requires plausible models of the distributions of the variables of interest and suitably randomized designs by which the sample data are obtained. Inferential test are prefaced by hypotheses or models, and the tests compute the probabilities, *P*, that the hypotheses are true or that the data do comply with the proposed models. Two common tests, the *z* test for comparing individual values with population statistics and the *F* test in the analysis of variance for comparing mean values, are based on underlying normal distributions. They are robust against small departures from that distribution, and tests for normality have little merit; histograms and Q–Q graphs of residuals are better guides. The American Statistical Association recently set out six principles for reporting probabilities from inferential tests. It recommended complete transparency, with *P* values placed on a continuous scale instead of more or less than the conventional significance at $P \leq 0.05$. Computed values of *P* should be reported along with estimated means and their standard errors. Readers and clients can then judge for themselves whether statistically significant results are scientifically significant or practically important.

Statistical Outliers

Mehala Balamurali and Raymond Leung
Rio Tinto Centre for Mine Automation, Australian Centre for Field Robotics, Faculty of Engineering, The University of Sydney, Sydney, NSW, Australia

Definitions

Outliers refer to data points that differ significantly from other observations (Grubbs 1969). Although extreme values can

occur by chance from any distribution, the outliers encountered during mining are mainly the result of collecting assay samples from adjacent domains with contrasting composition to the targeted domain; these outliers are included unintentionally due to inaccurate geological domain boundary definitions. Henceforth, the term *sample* (or assay sample) is used synonymously with *data point*. For clarity, each sample is represented by a p -dimensional vector which measures the concentration of p geochemical components at one location, as opposed to repeated measurements over a set of random variables in the context of a dynamical system. Statistically, outliers may be considered as values that derive from another process or source (Hampel et al. 2011; Barnett and Lewis 1994). In this exposition, outliers are assumed to belong to a separate population and their attributes are expected to be vastly different to the data points sampled from the main population.

Impact of Outliers in Geological Domaining

In open pit mining, the accuracy of grade estimation is impacted by the existence of outliers within a geological domain. The presence of outliers contributes directly to interpolation errors of the grade in the form of overestimation or underestimation. This bias not only undermines confidence and grade control efforts, it also has a flow-on effect on the execution of subsequent mining processes and ability to adhere to production targets. Significantly, mine planning and excavation activities are informed by the grade prediction model. Hence, artifacts and inaccuracies in the model caused by outliers can ultimately affect the efficiency and profitability of the overall mining operation.

An integral part of standard mine practice is interpreting the deposits into geological domains. Geological domains are used to group correlated geochemical data together for sectional interpretation and 3D modeling purposes, particularly where there is lack of continuity between different parts of the region. These domains are further used to ensure that all the grades spatially located in a modeling unit are grouped together for grade estimation of that unit. Geological domain definitions are derived from exploration and blast-hole data. These observations often involve a dozen or so variables. They are also subject to estimation errors and measurement noise. The true extent depends on the quality of the mining program and various controls which affect how ore samples are collected and assayed. Principally, outliers occur because samples are mistakenly included from outside the target domain. Techniques for rectifying such errors have been proposed in (Leung et al. 2022), but these lie outside the scope of the current discussion. Acknowledging that incorrect grouping of samples inevitably occurs, attention is turned to identifying the outliers.

Outliers may be mingled with the target domain data for a variety of reasons. Some outliers are just bad data that arise due to logging, sampling, or calibration errors. Irrespective of their origin, outliers can be handled in a passive or proactive way. Robust estimation techniques offer resilience and constitute the former, they implicitly ignore the influence of outliers and minimize their impact on statistical estimates and domain interpretations. Proactive approaches may additionally reclassify the removed outliers and consider whether the outliers collectively form meaningful subpopulations. This is useful when latent domains are present within the dominant (target) domain, it allows existing knowledge about an orebody to be updated and offers new insight. It presents an opportunity for new localized geological features to be discovered. Regardless of the motivations, identifying the outliers is an important first step.

In this summary of outlier detection work, we will discuss (1) multivariate outlier detection methods, (2) t-SNE-based subdomain detection, and (3) performance comparison of t-SNE and MCD with different sample truncation strategies. This study draws upon material from previously published works that focus on iron ore mining in the Pilbara region in Western Australia.

Techniques: Multivariate Outlier Detection in Geochemical Data

Traditional methods for identifying univariate and bivariate outliers are well known to geologists (Rousseeuw and Leroy 1987; Barnett and Lewis 1994). However, detection of multivariate outliers is still an active research area. Although outlier detection can be applied to individual variables in multivariate geochemical data (Reimann et al. 2005; Filzmoser et al. 2005), this is not generally advisable as it ignores the correlations (covariances) that exist between different components.

For univariate outlier detection, a simple approach that can be used is the standard deviation method. In geochemical analysis, values that fall outside mean $\pm$ stdev are considered as extreme data points in (Hawkes and Webb 1962). Reimann et al. (2005) explained that geochemistry outliers are not often extreme values and instead originate from different, often superimposed, distributions associated with processes that are rare in the environment. Moments describing the data [mean $\pm$ stdev] work well when the data is really an extreme value, but the rule fails when the presence of outlier populations are relatively large in comparison to the target population.

Tukey (1977) proposed a test for screening outliers. A graphical tool is used to display the distribution of the univariate data by displaying its median, 25th percentile (lower quantile Q_1), 75th percentile (upper quantile Q_3). The

interquartile range is defined as $Q_3 - Q_1$ as in a boxplot. Inner fences and outer fences are defined by the interval $[Q_1 - k \times (Q_3 - Q_1), Q_3 + k \times (Q_3 - Q_1)]$ with $k = 1.5$ and $k = 3$, respectively. Any values outside the outer fences are shown as outliers in the graph.

Tukey's method is considerably effective compared with the standard deviation method. They both work well when the data is normally distributed. However, geochemical data often do not follow normality and instead are skewed in one direction. Thus, their distribution is nearly a lognormal distribution (Iglewicz and Hoaglin 1993). The outliers can be identified from transformed distribution. Tukey's method identifies outliers when the distribution is skewed because it makes no assumption about the distribution. However, in Tukey's approach, more points are detected as outliers when the data is highly skewed; the method may fail when the sample size is small.

Many others have studied the problem of univariate outlier detection. A recurring theme is that univariate extreme points are identified based on a significantly increased distance from the center of the data compared to the other points (inliers). Unlike univariate outliers, multivariate outliers are identified as distant points from a robust ellipse or multidimensional cloud that retain samples – the majority – which are in agreement (Gnanadesikan and Kettenring 1972; Rousseeuw and Leroy 1987; Barnett and Lewis 1994). In the literature, there is a general recognition that clusters of similar compositions can be identified more effectively in subspaces rather than in a full dimensional space as outliers (Strehl and Ghosh 2002).

Univariate outlier detection is generally inadequate for identifying multivariate outliers in geochemical data. Concretely, a data point may look extreme and deviate enough with respect to one or more variables for it to satisfy the independent requirements of univariate outlier, yet the criteria of a multivariate outlier may not be automatically satisfied when all variables (geochemical components) are jointly considered. In univariate outlier detection, distance to the center

is used; but in multivariate outlier detection, both distance and structure of the data are needed (Rousseeuw 1985). Several methods for measuring dispersion in multivariate data are presented next.

Classical Mahalanobis Distance

The Mahalanobis distance measures how far a point $\mathbf{x}$ is from the mean of a dataset (Mahalanobis 1936; De Maesschalck et al. 2000). For multivariate outlier detection, the squared Mahalanobis distance is given by

$$D^2(\mathbf{x}, \bar{\mathbf{x}}) = (\mathbf{x} - \bar{\mathbf{x}})^T S^{-1} (\mathbf{x} - \bar{\mathbf{x}}) \quad (1)$$

In this equation, $\mathbf{x}$ denotes a single observation and $\bar{\mathbf{x}}$ denotes the centroid; both are p -dimensional vectors. A dataset comprises n observations (assay samples) and p features (variables). Each element in $\bar{\mathbf{x}}$ represents the mean concentration of a chemical component. If matrix X holds the original data with columns centered by their means, then the $p \times p$ covariance matrix may be computed as $S = X^T X / (n - 1)$.

An observation with a Mahalanobis distance $D^2(\mathbf{x}, \bar{\mathbf{x}}) > k$ is regarded as an outlier. Figure 1 provides a visualization of the univariate and bivariate distance measures. In the univariate case, distance is measured by $z = (x - \bar{x}) s^{-1}$, where s is the sample standard deviation. Points with high z -scores are treated as outliers. In the multivariate case, outlier detection considers patterns between all variables. Since the Mahalanobis distance is sensitive to outliers, Rousseeuw (1985) described a method for removing outliers (i.e., retaining representative samples) in a given domain to minimize the impact of outliers on the S estimate. This estimator is robust as it uses only a subset of observations (the h points) with the smallest covariance determinant. The z -score-bivariate analogy generalizes to higher dimensions via the Mahalanobis distance. Assuming the data distribution is multivariate Gaussian [for compositional data such as chemical assays, this is only approximately true after log-ratio

Statistical Outliers, Fig. 1 Left: univariate (standard normal deviate). Right: bivariate (generalized distance) distance measures

transformation is applied], it has been shown that the distribution of the Mahalanobis distance behaves as a chi-square distribution given a large number of samples (Garrett 1989). Therefore, a popular choice for the proposed cutoff point is $k = \chi^2_{(p, 1-\alpha)}$, where χ^2 stands for the chi-square distribution and α is the significance level – usually taken as 0.025 (Rousseeuw 1985).

Minimum Volume Ellipsoid

The minimum volume ellipsoid (MVE) estimator finds the mean ($\bar{\mathbf{x}}_J^*$) and covariance (S_J^*) from $h(\leq n)$ points that minimize the volume of the enclosing ellipsoid. This ellipsoid is computed from the covariance matrix associated with the subsample. Formally, $MVE(X) \rightarrow (\bar{\mathbf{x}}_J^*, S_J^*)$ where the optimal set $\{X_i | X_i \in J\}$ satisfies

$$\text{volume}(\text{ellipsoid}(S_J^*)) \leq \text{volume}(\text{ellipsoid}(S_K^*)) \quad (2)$$

for all observation subsets $K \neq J$ with $\#(J) = \#(K) = h$.

Concretely, X_i denotes the i^{th} row (or assay sample) in the observation matrix X . We interpret J as a collection of h row vectors from X such that the ellipsoid fitted to the data (i) passes through $p + 1$ data points, (ii) contains the h observations, and (iii) has the smallest volume among all sets K with cardinality h that also satisfy conditions (i) and (ii). By construction, outliers must be excluded from the set J . Typically, $h = [(n + p + 1)/2]$.

Minimum Covariance Determinant

The minimum covariance determinant (MCD) estimator finds the robust mean and covariance from $h(\leq n)$ points that minimize the determinant of the covariance matrix associated with the subsample. It looks for an ellipsoid with the smallest volume that encompasses the h data points. Formally, $MCD(X) \rightarrow (\bar{\mathbf{x}}_J^*, S_J^*)$ where the optimal set $\{X_i | X_i \in J\}$ satisfies

$$|S_J^*| \leq |S_K^*| \quad \forall \text{ subsets } K \neq J \text{ with } \#(J) = \#(K) = h. \quad (3)$$

In other words, J minimizes the volume of the ellipsoid among all subsets K that contain h observations from X . Note: $|S_J^*|$ is used as a proxy measure since the actual volume is proportional to $\det(S_J^*)$.

Obtaining the center and covariance estimates in the Mahalanobis distance using the MCD estimator produces a robust distance measure that is not skewed by outliers. Meanwhile, outliers will continue to possess large values based on this robust distance measure. The most common cutoff value k selected for the $D^2(\mathbf{x}, \bar{\mathbf{x}}) > k$ test is again based on chi-square critical values. The chi-square Q-Q plot provides a useful way to visually assess whether distances are χ_p^2

distributed. To generate a plot of robust distance versus estimated percentiles, data points are ordered according to their Mahalanobis distances, and paired up with an ordered sequence of χ_p^2 percentiles which may be obtained by drawing n samples from a chi-square distribution with p degrees of freedom. If the data is from a multivariate normal distribution, then the data points should be on a straight line. However, points with a higher Mahalanobis distance than the chi-square quantiles do not follow a straight line trend, thus they are treated as outliers.

Application: Multivariate Outlier Detection in the Context of Iron Ore Mining in Western Australia

In mining, assay analysis is performed routinely to determine the geochemical composition of subterranean ore bodies. This is achieved by sampling material extracted from drilled holes. In the context of iron ore mining in the Pilbara region in Western Australia (Fig. 2), the chemical components of interest include Fe, SiO₂, Al₂O₃, P, LOI, S, MgO, Mn, TiO₂, and CaO. These measurements constitute a point cloud in a high-dimensional space which makes it more difficult to articulate meaningful differences between samples that belong to different geological domains.

Balamurali and Melkumyan (2015) evaluated the standard classical Mahalanobis distance method and the robust distance methods: *minimum volume ellipsoid* (MVE) and *minimum covariance determinant* (MCD), to find the presence of outliers in the given geological domain. The study further evaluated the methods with different contamination levels and concluded that the robust methods outperform the classical Mahalanobis distance-based approach. However, the performance of robust methods tends to decrease with increasing contamination levels. The authors introduced ratios between the weight percentage (wt%) of chemical grades: SiO₂/Al₂O₃, LOI/Al₂O₃, and TiO₂/Fe as additional variables, and observed a significant increase in the outlier detection rate even with a high contamination level (Fig. 3).

In addition, Gaussian process classification and the chi-square Q-Q plot were tested to gain insight with respect to finding abnormal data points. Not surprisingly, some of the multivariate outliers identified were not detected as univariate outliers. On the other hand, univariate outliers pertaining to trace elements (nondominant chemical components) may trigger false positives when the samples themselves are not considered multivariate outliers.

Ensembles of Subsets of Variables

In order to further understand the influence of raw chemical variables and the ratios between the variables in outlier detection, a novel method of outlier detection was proposed in (Balamurali and Melkumyan 2018) using ensembles of

Statistical Outliers, Fig. 2 Geological overview of the Pilbara region in Western Australia. The economically valuable banded-iron formations are hosted mainly by the Hamersley Group of the Mount Bruce Supergroup © Commonwealth of Australia (Geoscience Australia) 2021

subsets of variables (EoSV). This study extended the previous work by incorporating a variable selection method. Similar to the work that incorporated three additional variables, in this work, all possible combinations of ratios between the raw chemical variables were used as additional variables. The Tree Bagger (Breiman 1998) method was used to combine features that have a large discrimination power at different contamination levels. Previous studies recognized that feature engineering can significantly improve training and model prediction outcomes (Mitra et al. 2002; Saeys et al. 2007).

The EoSV method demonstrated that the relevance of features varies with contamination level in the outlier classification problem. Hence, the stability of the influence of features was assessed and a method was proposed to keep only the features with stable influences in outlier detection.

t-Distributed Stochastic Neighbor Embedding (t-SNE) for Outlier Detection

Although multivariate outlier identification is important, it is a means rather than an end. Very often, there is value in

Statistical Outliers, Fig. 3 Comparing robust outlier detection methods using MCD with different feature combinations (Reference: Balamurali and Melkumyan (2018))

retaining the outliers for further analysis. When the outliers are viewed in the context of the raw and filtered data, spatial clustering may emerge. These clusters may suggest the existence of latent domains and highlight locations where the existing domain boundary is possibly incorrect.

Figure 4 demonstrates a successful application of t-SNE (Van der Maaten and Hinton 2008) to outlier identification. The proposed method combines the t-SNE dimensionality reduction technique with spectral clustering (Von Luxburg 2007) to uncover persistent outliers. Figure 4 (top) shows two random realizations of the t-SNE and the chemical signatures of two clusters in the t-SNE domain. The smaller cluster corresponds to outliers sampled from a spatially adjacent geological domain (see Fig. 4 bottom). These green points are chemically distinct from the main population (target domain) and they are spatially correlated. By projecting the assay data to two or three dimensions, t-SNE allows geochemical differences between the main population and outliers to be visualized in a scatter plot and meaningful geological domain clusters to be discerned (Balamurali and Melkumyan 2016).

Although t-SNE was successfully used in identifying sub-populations, because of its stochastic nature, t-SNE provides different results in different runs (Fig. 4). In order to produce stable results, the authors proposed a novel methodology for

ensemble clustering based on t-distributed stochastic neighbor embedding (EC-tSNE) to extract persistent patterns that more reliably correlate with geologically meaningful clusters (Balamurali and Melkumyan 2020). The proposed method uses silhouette scores to select the optimal number of clusters to cancel out inconsistency. EC-tSNE uses a consensus matrix (Monti et al. 2003) and agglomerative hierarchical clustering to achieve this. A map of multivariate outliers (see Fig. 4 bottom-left) can clearly identify the “contaminated” sites where samples are collected outside the target domain and potential contamination (or dilution) of high-grade ore material may occur.

MCD Outlier Detection with Sample Truncation Strategy

Following the experiments on EC-tSNE, Leung et al. (2019) proposed two sample truncation methods: *maximum hull distance* and *maximum silhouette*, to reject outliers in multivariate geochemical data. This builds on the foundation where two essential points remain unchanged: (i) the distance between samples is computed using robust estimators and (ii) outliers manifest as points that are a long distance away from the consensus values such as the robust mean obtained from the sampled population. The key observation is that outliers are relegated to the upper tail region when points are sorted by their robust distances in ascending order and

Statistical Outliers, Fig. 4 Top row: Results from t-SNE spectral clustering are displayed in t-SNE coordinates for two random runs. Bottom row (left): corresponding results in spatial coordinates; (right)

the normalized Fe grade of samples determined by geochemical assays (Reference: Leung et al. (2019))

plotted in a chi-square quantile plot. Sample truncation simply refers to the action of removing samples from this ordered sequence beyond a certain cutoff point (see Fig. 5). This approach allows the outlier removal decision to be made after the points are sorted by their robust distances; it also provides flexibility as the rejection threshold may be chosen by a domain expert or computed automatically to reduce false negatives, for instance. Traditionally, a fixed threshold based on the chi-square critical value, $\chi^2_{p,1-\alpha}$, is used for MCD. For compositional data analysis, this choice may result in sub-optimal outlier rejection. Figure 5 illustrates the improvement that may be obtained using one of the proposed MCD sample truncation strategies, where threshold A and B correspond to choosing $D \leq \sqrt{\chi^2_{p,1-\alpha}}$ and the proposed cut-off value, respectively. For the former, the extent of outlier removal is clearly inadequate. The outliers identified using MCD were compared to the EC-tSNE results in (Leung et al. 2019) and the MCD sample truncation strategies were recommended as

an alternative to EC-tSNE since t-SNE is computationally costly even for datasets of a moderate size ($n > 10$ k).

Summary

This chapter described the fundamental characteristics of multivariate outliers, focusing specifically on a scenario most often encountered during mining whereby outliers result from collecting assay samples from an adjacent rather than the intended domain due to inaccurate domain boundary definitions. The presence of outliers can impact the performance of grade prediction models and this has far-reaching consequences for grade control and mine planning as it affects target conformance, process efficiency, and profitability of a mining operation.

In the technical section, univariate and multivariate outlier identification methods were reviewed. This covered Tukey's method, the use of Mahalanobis distance, and robust

Statistical Outliers, Fig. 5 Outlier rejection based on MCD robust distance and threshold selection (Reference: Leung et al. (2019))

alternatives based on minimum volume ellipsoid (MVE). Additionally, more recent approaches based on ensemble clustering t-distributed stochastic neighbor embedding (EC-tSNE) and MCD robust distances were introduced. The importance of feature selection was highlighted. Using real geochemical assay data collected from a Pilbara iron ore mine; the case study demonstrated successful extraction of outliers using both EC t-SNE and MCD robust distances. When spatially coherent outlier clusters emerge, latent domains and the areas where domain boundary delineation is poor can both be identified. This can give potentially new insight and local knowledge into the structural geology.

While there is no universal outlier detection method that works in all circumstances, the MCD robust distance approach combined with appropriate threshold selection strategies seems to offer promising results, in terms of efficiency and efficacy. At the very least, it allows outliers to be segregated and, if necessary, modeled as a separate process (or latent domain) during grade estimation.

Statistical Quality Control

Jörg Benndorf
TU Bergakademie Freiberg, Freiberg, Germany

Definition

Statistical quality control (SQC) is the application of statistical methods and optimization to monitor and maintain the quality of products and services. Two branches of SQC are distinguished. The first one is concerned about the quality of particular product items and refers to the name acceptance sampling. Here, a decision is made to either accept or reject the items based on their quality. The second branch is

concerned about controlling the process in such a way to guarantee the on spec quality of the products and is referred to as statistical process control. It typically includes the steps (1) establishment of expected performance indicators, (2) targeted process monitoring, (3) comparison between observed and expected performance, and (4) corrective adjustment of process control parameters and decisions.

Although, initially developed for manufacturing industry in the 1920s and then intensively applied during World War II, the principles of SQC found its way in many non-manufacturing applications, also in earth sciences (e.g., Montgomery 2020). As a part of a quality management system to fulfill quality requirements, today, SQC can be a key constituent to implement ISO 9000/ISO 9001 – quality management system standards.

Acceptance Sampling

The idea of acceptance sampling is to choose a representative sample of a product lot and test for defects. If the number of defects exceeds a certain acceptance criterion, the product lot is rejected. The underlying sampling plan is based on a hypothesis test and involves the following steps:

- Step 1: Definition of the size of the product lot to be samples
- Step 2: Definition of a representative random sample size for the lot
- Step 3: Definition of an acceptance criterion for not rejecting the lot (number of defects)

The null-hypothesis H_0 is that the lot is of acceptable quality. The alternative hypothesis H_A is that the lot is not of acceptable quality. There are two types of risks associated with acceptance sampling:

- The lot is rejected although it has the acceptable quality. This is referred to the type I error in statistical testing and is quantified by the error probability α .
- The lot is accepted although it is not of acceptable quality. This is referred to the type II error in statistical testing and is quantified by the error probability β .

A main decision in acceptance sampling is the number of required samples necessary to guarantee acceptable probabilities α and β while still reacting on a desired deviation limit. This number is defined based on the understanding of the product variability, the uncertainty in monitoring using the test statistical value. An example in a later section demonstrates this process.

Statistical Process Control

Statistical Process Control (SPC) is a methodology for measuring and controlling quality during the manufacturing process. It requires that quality data are obtained in the form of product or process observations in regular intervals or in real-time during manufacturing. This data is then plotted on a graph with predetermined control limits, the so-called control chart. Control limits are determined by the capability of the process, whereas specification limits are determined by the client's needs. A typical example of such a control chart is given in Fig. 1 for quality control of run-of-mine (ROM) ore. Control limits correspond to the 2σ and 3σ confidence intervals.

According to the founder of this technique, W.A. Shewhart, the variation observed within the process results from two sources (Shewhart 1931):

- Superposition of a number of sources of small variation and background noise (unavoidable)
- Large variability resulting from inaccuracies in process control caused by process defects such as imprecise working equipment or human error (avoidable)

A reactive process control is managed by the means of the control chart and the defined upper and lower limits. Typically and as illustrated in Fig. 1, limits are derived by statistical inspection of the sample population. The process is deemed "in control" if sample measurements are between the limits. Observations, which are close to the limits or even exceed these indicate the likely occurrence of avoidable causes within the process and call for a root cause analysis and corresponding corrective action. In this way, a so-called iterative Shewhart-cycle can be implemented, which consists of the following steps:

- Plan: Plan and design the process and establish expectations in form of process indicators.
- Do: Implement the design.
- Check: Monitor the process and identify differences between expectations and outcomes or statistical anomalies.
- Act: Adjust the process if deviations are significant.

This iterative cycle is often used to continuously monitor and adjust the process to guarantee the possible improvement of product quality.

Statistical Quality Control, Fig. 1 Example of a control chart

Application of Acceptance Sampling in Environmental Monitoring

One goal of environmental monitoring for any industrial activity is to check the compliance of emission or contamination levels with respect to restrictions imposed by permitting authorities or legislation. Restrictions can be defined in a way that the background contamination existing before the industrial activity starts should not increase significantly. In a sense of statistical quality control, environmental monitoring can be interpreted as a process to take a set of representative samples of a contamination or emission variable within a possible impacted area or domain. This is done to test if a contamination level at a given point in time is statistically and significantly increased compared to the background contamination. Sampling is repeated regularly as imposed by the application dynamics or the permitting requirements and also to understand possible timely trends.

An essential task of this type of environmental monitoring is to define the appropriate number of samples in space and in time to meet a desired quality of the applied hypothesis test (e.g., De Gruijter et al. 2006). The quality of the hypothesis test is defined by the acceptable levels of risks associated with the type I and type II error in acceptance sampling. Thus, the required number of samples is a direct function of the frequency distribution of the variable considered within the domain, the threshold of interest, and the error probabilities α and β are related to the statistical test.

Example

A simple example shall illustrate the reasoning behind this type of application. As part of an environmental impact assessment, the average Cd content of soil within a possible impacted area by mining activities is determined during baseline monitoring by a set of 50 randomly selected independent samples. The mean value of the data and the variance of the data are calculated according to Eqs. (1) and (2).

$$\bar{z} = \frac{1}{n} \sum_{i=1}^n z_i \quad (1)$$

$$\sigma^2(z) = \frac{1}{(n-1)} \sum_{i=1}^n (z_i - \bar{z})^2 \quad (2)$$

The standard deviation of the mean value is

$$\sigma(\bar{z}) = \sqrt{\frac{1}{n(n-1)} \sum_{i=1}^n (z_i - \bar{z})^2} \quad (3)$$

Applied to the sample values, a mean Cd content of $\bar{z}_0=0.20$ mg/kg with a standard deviation (mean) of $\sigma(\bar{z}_0) = \pm 0.02$ mg/kg has been obtained. The latter has been derived

based on the standard deviation of the samples of $\sigma(z)=\pm 0.14$ mg/kg.

After some months of operation, during a first monitoring epoch, the mean value has been determined again. This time, the mean Cd content is $\bar{z}_1 = 0.23$ mg/kg with a comparable standard deviation of the mean value $\sigma(\bar{z}_1) = \pm 0.02$.

The first obvious question is whether the Cd content has statistically significantly increased in comparison to the baseline monitoring or in other words: What is the difference between both mean values of systematic or random nature? To answer this question, we can start with the following thoughts:

The difference between the two mean values is distributed with an expectation of

$$\Delta = \mu_1 - \mu_0, \quad (4)$$

where μ_0 and μ_1 are the true mean values of the Cd content for the two epochs, and a standard deviation of

$$\sigma_{\bar{z}_1 - \bar{z}_0} = \sqrt{\sigma^2(\bar{z}_1) + \sigma^2(\bar{z}_0)}. \quad (5)$$

The resulting normalized standard variable is

$$z = \frac{\bar{z}_1 - \bar{z}_0 - (\mu_1 - \mu_0)}{\sqrt{\sigma^2(\bar{z}_1) + \sigma^2(\bar{z}_0)}} \quad (6)$$

To test, if the difference is of systematic or random nature, a null hypothesis

$$H_0 : \Delta_0 = \mu_1 - \mu_0 = 0 \quad (7)$$

can be formulated that assumes a zero difference between the mean Cd content of the baseline monitoring and monitoring epoch 1. The corresponding test statistical value is

$$z = \frac{\bar{z}_1 - \bar{z}_0 - (\Delta_0)}{\sqrt{\sigma^2(\bar{z}_1) + \sigma^2(\bar{z}_0)}} \quad (8)$$

This statistical test value is to be compared to the quantile of the standard normal distribution u that corresponds to the desired error probability α related to the type I error in statistical testing. Depending on whether the focus is on a change in general or a directed change (increase or decrease), a quantile of the standard normal distribution is chosen. This corresponds to either the $100-\alpha/2$ confidence interval or the $100-\alpha$ interval.

For the numeric example, we are interested in a change in general of the mean Cd content. With a desired error probability $\alpha = 5\%$, the corresponding quantile of the standard

Statistical Quality Control,**Fig. 2** Hypothesis test for change detection

normal distribution is $u_{100-\alpha/2}=1.96$. This value is compared to the test statistical value, which for the numerical example is $z = 1.06$. H_0 is accepted, if $z < u_{100-\alpha/2}$. Thus, in a sense of acceptance sampling, the quality of the product (the impact of the mining activity on the Cd content) is within the limits.

The second question is now related to the required number of samples to detect a change within a predefined detection limit with related error probabilities α and β . Figure 2 illustrates the case for a two-sided problem, that means a change in any direction, positive or negative, is to be detected.

The detection limit Δ_1 is equal to the difference between the true mean values of the Cd content $\mu_1 - \mu_0$. According to Fig. 2, the detection limit DL is obtained by summing up the quantiles of the confidence interval $100 - \alpha/2$ related to H_0 and β related to the alternative hypothesis H_A . Thus the detection limit is

$$DL = u_{100-\alpha/2} \cdot \sqrt{\sigma^2(\bar{z}_1) + \sigma^2(\bar{z}_0)} - u_\beta \cdot \sqrt{\sigma^2(\bar{z}_1) + \sigma^2(\bar{z}_0)}. \quad (9)$$

$u_{100-\alpha/2}$ quantile of the standard normal distribution related to a two-sided confidence level of $100 - \alpha$

u_β quantile of the standard normal distribution related to an error probability β (detection error)

Assuming $\alpha = 5\%$ and $\beta = 5\%$ and the standard deviation of the mean value for each epoch of being equals with $\sigma(\bar{z}) = \pm 0.02$ mg/kg, the detection limit is $DL = 0.10$ mg/kg.

What is now the minimum number of data n required to guarantee a certain detection limit, say $DL = 0.05$ mg/kg?

First, we assume that standard deviations of the mean value remain the same for two epochs

$$\sigma^2(\bar{z}_1) = \sigma^2(\bar{z}_2) = \sigma^2(\bar{z})$$

Solving Eq. (9) with respect to $\sigma^2(\bar{z})$ results in

$$\sigma(\bar{z}) = \frac{1}{\sqrt{2}} \left(\frac{DL}{u_{100-\alpha/2} - u_\beta} \right). \quad (10)$$

For the numerical example, a necessary standard deviation of the mean of $\sigma(\bar{z}) = \pm 0.01$ mg/kg is required. According to the relationship

$$\sigma(\bar{z})^2 = \frac{1}{n} \sigma^2(z) \quad (11)$$

and taking into account the standard deviation of the data of $\sigma(z) = \pm 0.14$ mg/kg, the required number of samples is approximately 200.

Application of SPC in Grade Control in Mining

A typical application of statistical quality control in the field of geosciences and geoenvironment is ore quality or grade control in mineral resource extraction. Benndorf (2020) documents a closed-loop framework to implement a real-time process monitoring and control framework for grade control in mineral resource exploitation. This is based on the plan-do-check-act (PDCA) iterative management cycle as suggested by Shewhart. It is general and applicable for surface mining and underground operations and can be interpreted as follows:

P – Plan and predict: Based on the mineral resource and grade control model, strategic long-term mine planning, short-term scheduling, and production control decisions are made. Performance indicators such as expected ore tonnage extracted per day, expected ore quality attributes, and process efficiency are predicted.

Statistical Quality Control,
Fig. 3 The real-time mining
 concept. (After Benndorf and
 Jansen 2017)

D – Do: The mine plan is executed.

C – Check: Production monitoring systems continuously deliver data about process indicators using modern sensor technology. For example, the grade attributes of the ore extracted are monitored using cross-belt scanners. Differences between model-based predictions from the planning stage and actual measured sensor data are detected.

A – Act: Differences between prediction and production monitoring are analyzed and root causes investigated. One root cause may be the uncertainty associated with the resource or grade control model to predict the expected performance. Another root cause may be the precision and accuracy of sensor measurements. Using innovative data assimilation methods (e.g., Wambeke et al. 2018), differences are then used to update the resource model and mine planning assumptions, such as ore losses and dilution. With the updated resource and planning model, decisions made in the planning stage may have to be reviewed and adjusted in order to maximize the process performance and meet production targets through the use of sophisticated optimization methods (e.g., Paduraru and Dimitrakopoulos 2018) (Fig. 3).

The two key requirements in this application of statistical process control to real-time grade control are the ability to update the resource/grade control model quickly and to derive fast new decisions based on the new model. Key enablers are techniques of data assimilation for resource model updating and mine planning optimization.

Conclusions

Natural variability is a key characteristic of any spatial or temporal process or variable considered in earth sciences.

Due to the interaction of humans with the geosphere, variables may change significantly over time. The ability to monitor impacts of anthropogenic activities with respect to environmental or economic indicators requires distinguishing between natural variability and systematic change. Techniques of SQC allow for a statistically sound judgment of this change by designing appropriate sampling strategies, not only to detect change but also to take corrective action in case some indicators drift away. The availability of online sensors and sensor networks in earth observation allows today for the implementation near real-time closed-loop concepts for transparent impact monitoring and process control. In this context, results of SQC provide the means of an objective and transparent communication of project impact.

Statistical Rock Physics

Gabor Korvin

Earth Science Department, King Fahd University of
Petroleum and Minerals, Dhahran, Kingdom of Saudi Arabia

Definition

Statistical Rock Physics is a part of Rock Physics (Petrophysics) where we use concepts, methods, and computational techniques borrowed from Stochastic Geometry and Statistical Physics to describe the interior geometry of rocks; to derive their effective physical properties based on their random composition and the random arrangement of their constituents; and to simulate geologic processes that had led to the present state of the rock.

Introduction

This chapter is about the novel computational tools used in Rock Physics, based on concepts, methods, and computational techniques borrowed from Stochastic Geometry and Statistical Physics. Most techniques that will be discussed belong to the toolbox of the “Digital Rock Physics” (DRP) technology of Core Analysis or the “Statistical Rock Physics” (SRP) procedure of Seismic Reservoir Characterization. My aim has been to help the reader to understand the claims and published results of these powerful new technologies, and – most importantly – to creatively apply stochastic geometry and statistical physics in their own research to other fields of rock physics. For this purpose, the theory discussed will be illustrated on diverse applications: hydraulic permeability, rock failure, NMR, contact forces in random sphere packings, compaction of shale, HC maturation. There are five sections, each with a few applications. Section “[Stochastic Geometry](#)”, introduces Gaussian Random Fields and the Kozeny-Carman equation (1.1), and then gives three applications: specific surface from 2D microscopic image, estimating tortuosity, and reconstructing 3D pore space from a 2D image (sections “[ACF \(Autocorrelation Function\) Based Estimates of the Specific Surface](#)”, “[The Random Geometry of Tortuous Flow Paths](#)”, and “[Reconstructing 3D Pore Space from 2D Sections](#)”). Section “[Maximum Entropy Methods](#)” is devoted to Maximum Entropy (ME). ME is explained in section “[The Maximum Entropy Method](#)”; section “[Maximum Entropy \(ME\) Pore Shape Inversion](#)” applies ME to pore-shape determination; section “Shale Compaction and Maximal Entropy” derives Athy’s empirical law of shale compaction from the ME principle; section “Contact Force Distribution in Granular Media” is about contact-force distribution in loose

granular packs. Section “[Self-Consistency and Effective Media](#)” treats the Effective Medium and Differential Effective Medium methods. EM is introduced on the example of random resistor networks in section “[Effective Medium \(EM\) Approximation](#)”, and DEM is illustrated by the iterative computation of the effective elastic moduli of porous or cracked rock in section “[Differential Effective Medium \(DEM\) Approximation](#)”. Section “[Thermodynamic Algorithms](#)” summarizes three important thermodynamic algorithms: random walk in section “[Random Walk](#)” (applications: spin magnetic relaxation, and electric conductivity in porous rocks); Lattice Boltzmann Method in section “[Lattice Boltzmann Methods for Flow in Porous Media](#)” (application: hydraulic flow); and Simulated Annealing (already introduced in section “[Reconstructing 3D Pore Space from 2D Sections](#)” as a technique for pore space reconstruction) is applied in section “[Simulated Annealing](#)” to find the thermal conductivity distribution of soil constituents. The last part, section “[Computational Phase Transitions](#)”, is on Computational Phase Transitions: section “[Percolation Theory](#)” deals with Percolation Theory (application: permeability of kaolinite-bearing sandstones); section “[Renormalization Group \(RNG\) Models of Rock Failure](#)” with the Renormalization Group (RNG) approach to rock failure; section “[Discrete Scale Invariance](#)” with determining the critical point of phase transition (based on Discrete Scale Invariance); the final section “[Arrhenius Law and Source-Rock Maturity](#)” is about how Arrhenius Law of Physical Chemistry is applied to estimate the maturation of source rocks.

Stochastic Geometry

Random Functions Along a Line, Random Fields, Kozeny-Carman Equation

A *random function*, $\{f(x)\}_\alpha$, is a family of functions depending on a random parameter α , where the independent variable x varies along some line. A given $f(x)$ picked at random from among all possible $\{f(x)\}_\alpha$ s is a *realization*. At some fixed point on the line x_1 , $f(x_1)$ is a *random value*, and it attains different values y with the probabilities $\text{Prob}[f(x_1) < y] = F(x_1, y)$. The following expected values (taken with respect to α , i.e., over all realizations of $\{f(x)\}_\alpha$) are often enough to characterize a random function: $\langle f(x_1) \rangle$, $\langle f^2(x_1) \rangle$, $\langle f(x_1) \cdot f(x_2) \rangle$, termed *mean value*, *mean square value*, and *autocorrelation function*. A random function is *translation invariant* if its statistical properties do not change with respect to a shift along the line; in particular, if $\langle f(x) \rangle = \langle f(0) \rangle$; $\langle f^2(x) \rangle = \langle f^2(0) \rangle$; $\langle f(x_1) \cdot f(x_2) \rangle = \langle f(0) \cdot f(x_2 - x_1) \rangle := R_{ff}[x_1 - x_2]$ where the function R_{ff} is the *autocorrelation function (ACF)* of $f(x)$. It is an *even function*, $R(\xi) = R(-\xi)$, assuming its maximum at $\xi = 0$, $R_{ff}(0) = \langle f^2(x) \rangle$. The *normalized autocorrelation function* is $\rho_{ff}(\xi) = R_{ff}(\xi)/\langle f^2(x) \rangle$.

If $\mathbf{x}(x,y)$ or $\mathbf{x}(x,y,z)$ is a point in two- resp. three-dimensional Euclidean space, then $\{f(x,y)\}_a$ resp. $\{f(x,y,z)\}_a$ are called *random fields* over the plane, or space, a given field $f(\mathbf{x})$ picked out at random is a *realization* of the field.

A random field is *homogeneous* if its statistical properties are invariant with respect to a shift, that is if $\langle f(\mathbf{x}) \rangle$ and $\langle f^2(\mathbf{x}) \rangle$ are constant, and the autocorrelation function only depends on the difference of $\mathbf{x}$ and $\mathbf{y}$ $\langle f(\mathbf{x})f(\mathbf{y}) \rangle = R_{ff}(\mathbf{x}, \mathbf{y}) \equiv R_{ff}(\mathbf{x} - \mathbf{y})$. If the statistical properties of the field are also invariant with respect to rotations and reflections, we speak about a *homogeneous and isotropic random field*. In such a field the autocorrelation is a function of the magnitude of $\mathbf{x} - \mathbf{y}$: $\langle f(\mathbf{x})f(\mathbf{y}) \rangle = R_{ff}(|\mathbf{x} - \mathbf{y}|)$. The autocorrelation function $R(r) = a^2 \exp(-r/r_0)$, where $r =$

$\sqrt{[(x_1 - y_1)^2 + (x_2 - y_2)^2 + (z_1 - z_2)^2]}$, belongs to an isotropic field, and r_0 is the *correlation distance*, that is the value of r for which the autocorrelation function decreases to $1/e$ times its value at $r = 0$.

Most rock-physical applications of random geometry are related to the *Kozeny-Carman (KC) Equation* which expresses the permeability of a porous sedimentary rock as

$$k = \frac{1}{b} \Phi^3 \frac{1}{S_{\text{spec}}^2} \frac{1}{\tau^2} \quad (1)$$

where b is a shape factor (of the pore throats) of order one, $\Phi \in [0, 1]$ is porosity, S_{spec} is *specific surface*, the dimensionless parameter τ is called *hydraulic tortuosity*,

$$\tau = \frac{\langle L_{\text{hydr}} \rangle}{L} \geq 1$$

where $\langle L_{\text{hydr}} \rangle$ is the average hydraulic path length between two points a distance L . Combining $\frac{1}{b\tau^2}$ to a single constant C , the KC equation is expressed as

$$k = C \frac{\Phi^3}{S_{\text{spec}}^2}. \quad (2)$$

There are three concepts of specific surface: S_{spec} = surface area per unit bulk volume of the rock; S_0 = surface area per unit volume of solid material; S_p = surface area per unit volume of pore space. For any arrangement consisting of spherical grains of the same radius r one has

$$S_{\text{spec}} = (1 - \Phi)S_0; S_{\text{spec}} = \Phi S_p; S_p = \frac{1 - \Phi}{\Phi} S_0. \quad (3)$$

(Φ is porosity) and the KC equation can be written in three forms

$$k = C \frac{\Phi^3}{S_{\text{spec}}^2} \quad (4a)$$

$$k = C \frac{\Phi^3}{(1 - \Phi)^2 S_0^2} \quad (4b)$$

$$k = C \frac{\Phi}{S_p^2} \quad (4c)$$

where

$$C = \frac{1}{b\tau^2}. \quad (4d)$$

An important geometric theorem (Debye's theorem, see Korvin 2016) about specific surface area S_p (surface area per unit volume of pore space) states that *Select in a 2D image of an isotropic porous rock two randomly placed points A and B a distance r apart, where r is small, $r \ll 1$. Then the probability that A and B are in different media (i.e., one is in a pore, the other in a grain) is*

$$S_p \cdot \frac{r}{2} \quad (5)$$

ACF (Autocorrelation Function) Based Estimates of the Specific Surface

A plane section of the rock can be represented as a map of binary values

$$P(x,y) = \begin{cases} 1 & \text{if } (x,y) \in \Pi \\ 0 & \text{if } (x,y) \notin \Pi \end{cases}$$

where Π is the total set of pores in the microscopic image of the rock. $P(x,y)$ is the *characteristic function* of the pores. Assume that $P(x,y)$ is a translation invariant and isotropic random field. If Φ is the overall porosity, a randomly selected point (x,y) is with probability Φ in pore, with probability $1 - \Phi$ in the rock matrix. Taking expected values over different realizations of $P(x,y)$, the mean and variance of $P(x,y)$ are

$$\langle P(x,y) \rangle = \Phi \cdot 1 + (1 - \Phi) \cdot 0 = \Phi$$

$$\begin{aligned} \langle [P(x,y) - \Phi]^2 \rangle &= \langle P^2(x,y) - 2\Phi P(x,y) + \Phi^2 \rangle = \Phi - \Phi^2 \\ &= \Phi(1 - \Phi). \end{aligned}$$

In case of translation- and rotation invariance of $P(x,y)$ its normalized *Autocorrelation Function*

$\rho_{PP}(\xi, \eta)$ only depends on $r = \sqrt{\xi^2 + \eta^2}$:

$$\rho_{PP}(\xi, \eta) = \frac{\langle [P(x, y) - \Phi] \times [P(x + \xi, y + \eta) - \Phi] \rangle}{\langle [P(x, y) - \Phi]^2 \rangle} = \rho_{PP}(r).$$

Using Debye's theorem (Eq. 5), the specific surface of the pore boundaries can be estimated from the slope of the ACF $\rho_{PP}(r)$ at $r = 0$ as

$$S_p = -4 \frac{d}{dr} \rho_{PP}(r) \Big|_{r=0}. \quad (6)$$

Using the Kozeny-Carman Eq. (4) and assuming reasonable default values for shape factor b and tortuosity τ , Eq. (6) can be used to predict permeability from the ACF of the microscopic image. If the characteristic function $P(x, y)$ of the pore space has an exponential ACF with correlation distance r_0 , that is, if $\rho_{PP}(r) = \exp\left[-\frac{r}{r_0}\right]$, we get $S_{\text{spec}} = \frac{4}{\rho_0}$ and using this in the KC equation gives

$$k = \text{const} \cdot \Phi^3 r_0^2. \quad (7)$$

The exponential ACF $\rho(r) = \exp\left[-\frac{r}{r_0}\right]$ works well for ordinary black-and-white photographs, but for microscopic images of sedimentary rock a *stretched exponential* function

$$\rho(r) = \exp\left[-\left(\frac{r}{r_0}\right)^n\right] \quad (8)$$

has been found (Ioannidis et al. 1996) to better describe the measured ACF. Here r_0 is the correlation distance, and n a positive real exponent. The derivative of this ACF at $r = 0$ is $\frac{d}{dr} \rho(r) \Big|_{r=0} = -\frac{n}{r_0} r^{n-1} \Big|_{r=0}$ which, except for $n = 1$, cannot express the specific surface by means of Eq. (6) because for $n < 1$ it is divergent, while for $n > 1$ it is zero. To avoid this difficulty, one can use an *average correlation distance*

$$I_S = \int_0^\infty \rho(r) dr = \int_0^\infty \exp\left[-\left(\frac{r}{r_0}\right)^n\right] dr = \frac{r_0}{n} \Gamma\left(\frac{1}{n}\right) \quad (9)$$

and, instead of using (Eq. 7), which was valid for the ACF $R(r) = \exp\left[-\frac{r}{r_0}\right]$, expresses permeability as $k = \text{const} \cdot \Phi^B I_S^C$, that is,

$$\log k = A + B \cdot \log \Phi + C \cdot \log I_S \quad (10)$$

To find the value of $I_S = \frac{r_0}{n} \Gamma\left(\frac{1}{n}\right)$, one needs the correlation distance r_0 and the stretching exponent n , for which precise

estimates of Φ and of the ACF are needed. A practical problem that arises here is the *thresholding* of the images, that is, distinguishing pores from grains.

The Random Geometry of Tortuous Flow Paths

A simple scaling argument (Korvin 2016) shows that the hydraulic tortuosity in 2D sections of granular porous sedimentary rocks is an increasing function of grain size, while it decreases with porosity. Let L be the vertical size of the section considered (assuming that flow goes from top to bottom); Φ porosity (in fraction); τ tortuosity; r_0 , P_0 , A_0 characteristic size, characteristic perimeter, characteristic area of the grains in the 2D cross section; Z average number of pores adjacent to a grain (in the 2D section). We shall denote by $D_{P/A}$ the exponent in the celebrated Mandelbrot's *perimeter-area scaling law* (Mandelbrot 1982) applied to the grains in the microscopic 2D section:

$$P = P_0 \left(\frac{\sqrt{A}}{\sqrt{\pi} r_0} \right)^{D_{P/A}} \quad (11)$$

We proceed to show that *the average tortuosity of a flow path from top to bottom is given by*

$$\left\langle \frac{L_{\text{hydr}}}{L} \right\rangle = \tau = \Phi + \frac{(1 - \Phi)}{Z} \left(\frac{P_0}{r_0} \right) \left(\frac{\sqrt{A}}{r_0 \sqrt{\pi}} \right)^{D_{P/A}} \quad (12)$$

Note the special cases of Eq. (12). For $\Phi = 1$ we have $\tau = 1$; for $\Phi = 0$ there are no pores at all, the grain/pore coordination number is $Z = 0$ and consequently $\tau = \infty$ as it should be (see section “[Percolation Theory](#)”; Korvin 1992b).

Along a randomly selected vertical line of length L a part ΦL of the line goes through pore space. In these parts the flow goes along straight line segments. The remaining $(1 - \Phi)L$ length of the vertical line is filled by grains, and the fluid would cross $\frac{(1 - \Phi)L}{r_0}$ grains if it could go straight. But it cannot, because every time it reaches a grain it changes direction and continues in a “throat” following the curvature of the grain's periphery. By the definition of *coordination number* Z , the periphery P of a grain is adjacent to Z other grains, so that every individual “detour” adds a length $\left(\frac{P}{Z}\right)$ to the hydraulic path. This length of the detour is, by Mandelbrot's Eq. (11), equal to $\left(\frac{P}{Z}\right) = \frac{P_0}{Z} \left(\frac{\sqrt{A}}{r_0 \sqrt{\pi}} \right)^{D_{P/A}}$. As there are $\frac{(1 - \Phi)L}{r_0}$ such detours, the average tortuosity down to the bottom is indeed $\left\langle \frac{L_{\text{hydr}}}{L} \right\rangle = \tau = \Phi + \frac{(1 - \Phi)}{Z} \left(\frac{P_0}{r_0} \right) \left(\frac{\sqrt{A}}{r_0 \sqrt{\pi}} \right)^{D_{P/A}}$. Equation (12) compares fairly well with other theoretical predictions (Matyka et al. 2008) of the dependence of tortuosity on porosity. In a published *Lattice Gas (LG)* model $\tau = 0.8(1 - \Phi) + 1$; in a *percolation model* $\tau = 1 + a \frac{(1 - \Phi)}{(\Phi - \Phi_c)^m}$ (a and m are fitting parameters, Φ_c is the percolation threshold). The rule $\tau = \Phi^{-p}$ for Archie's *electric tortuosity*, or $\tau \approx 1 - p \log \Phi$ (p is

a fitting parameter; “log” will denote *natural logarithm* from now on) was obtained for cube-shaped grains and in theoretical studies on diffusive transport in porous systems composed of freely overlapping spheres, the empirical relation $\tau = 1 + p(1 - \Phi)$ was found for sandy or clay-silt sediments, and $\tau = [1 + p(1 - \Phi)]^2$ was reported for marine muds.

Reconstructing 3D Pore Space from 2D Sections

In this technique, statistical information, obtained from binary images of thin-sections, is used to create a 3D representation of the porous structure. The resulting 3D model honors the statistics of the thin sections, and is used to determine the topological attributes and effective physical properties of the rock. A powerful reconstruction algorithm of this kind employs an optimization technique imitating a thermodynamic process (*Simulated Annealing*, Yeong and Torquato 1998; see section “*Simulated Annealing*”).

The statistical properties needed are the first two moments of the characteristic function $\chi(\vec{r})$ (which is unity if $\vec{r}$ lies in the pore space, and zero otherwise): the porosity, $\Phi = \langle \chi(\vec{r}) \rangle$, and the normalized autocorrelation function, $\rho(\vec{u}) = \frac{\langle [\chi(\vec{r}) - \Phi][\chi(\vec{r} + \vec{u}) - \Phi] \rangle}{\Phi(1 - \Phi)}$. The ACF is fitted by the model $\rho(u) = \exp[-(u/r_0)^n]$, where $u = |\vec{u}|$, r_0 is a characteristic length scale (correlation length), and n is an adjustable parameter. In each iteration step i we compute the “energy” function $E_i(\rho) = \sum_k [\rho_i(u_k) - \rho_{ref}(u_i)]^2$ which is to be minimized, where $\{u_i\} = \{0, \Delta u, 2\Delta u, \dots\}$ is the digitized argument of the ACF, $\rho_i(u)$ is the actually observed ACF in this iteration step, $\rho_{ref}(u)$ is the ACF of the field to be reconstructed. Starting from a random configuration with porosity Φ , two voxels of different phases are exchanged at each iteration step. Thus Φ remains constant. The new configuration is accepted with the probability P given by the Metropolis rule

$$P = \begin{cases} 1 & \text{if } E_i \leq E_{i-1} \\ \exp[(E_{i-1} - E_i)/T] & \text{if } E_i > E_{i-1} \end{cases}$$

where T plays the role of temperature. In case of rejection, the old configuration is restored. By decreasing T , fields f_i with minimal energy $E_i(\rho)$ will be generated, that is their correlation properties will be similar to that of the reference field f_{ref} .

A 3D pore space can be transformed to a network of nodes (pore bodies) connected by bonds (pore channels, throats). In the most commonly used method one applies a 3D *morphological thinning algorithm* to extract the pores’ medial axes for the skeleton of the pore space. The network model is useful to determine the rock’s local and overall connectivity properties. Local connectivity is expressed by the pore’s

coordination number Z_c , defined as the number of throats connected to the given pore. The connectivity of a volume V of the rock is measured by its *specific genus* G_V , $G_V = G/V = (b - n + 1)/V$ where b and n are the number of branches and nodes in the pore network (see Korvin 1992b: 302–303). The parameter $G = b - n + 1$ is the maximal number of independent paths between two points in pore space, that is, the maximum number of independent cuts that can be made in the branches of the network without disconnecting it into separate networks. (Only pores with $Z \geq 3$ are considered “nodes” in the topological context.) For large networks, the genus per node G_0 is related to average coordination number by $G_0 = (\langle Z_{\geq 3} \rangle / 2) - 1$.

Maximum Entropy Methods

The Maximum Entropy Method

Suppose a measurable rock property λ can assume values belonging to L distinct ranges $\Lambda_1, \dots, \Lambda_L$. If we measure λ on a large number N of samples, we will find N_1 values in range $\Lambda_1, \dots, N_L$ values in range Λ_L . Letting $p_i = N_i/N$, the set of numbers

$$\{p_1, p_2, \dots, p_L\}, p_i \geq 0, \sum_{i=1}^L p_i = 1 \quad (13)$$

constitute a *discrete probability distribution*. It can represent different degrees of randomness: the distribution $p_1 = 1, p_2 = p_3 = \dots = p_L = 0$ is *not random*; the distribution $p_1 = \frac{1}{2}, p_2 = \frac{1}{2}, p_3 = \dots = p_L = 0$ is *not too random*, the distribution where all lithologies are equally possible, $p_1 = p_2 = p_3 = \dots = p_L = \frac{1}{L}$ is the *most random*. To characterize quantitatively the “randomness” of the distribution $\{p_1, p_2, \dots, p_L\}$, count how many ways one can classify the N samples such that $N_1 = p_1 N$ belongs to $\Lambda_1, N_2 = p_2 N$ to $\Lambda_2, \dots,$

$N_L = p_L N$ to Λ_L . The number of such classifications is given by

$$\Pi = \frac{N!}{N_1! N_2! \dots N_L!} \quad (14)$$

The larger is Π , the more random the distribution. Instead of Π it is easier to estimate $\log \Pi$ (“log” always means natural logarithm in this chapter),

$$\log \Pi = \log N! - \log N_1! - \dots - \log N_L! \quad (15)$$

If $n \gg 1$ we have the approximate Stirling’s formula

$$\begin{aligned}
\log(n!) &= \log(1 \cdot 2 \cdot 3 \cdots n) \\
&= \log 1 + \log 2 + \log 3 + \cdots + \log n \\
&\approx \int_1^n \log x dx = n \log n - n \sim n \log n
\end{aligned} \quad (16)$$

Using this approximation in Eq. (15):

$$\begin{aligned}
\log \Pi &\sim N \log N - \sum_{i=1}^L N_i \log N_i = - \sum_{i=1}^L N_i \log \frac{N_i}{N} \\
&= -N \sum_{i=1}^L \frac{N_i}{N} \log \frac{N_i}{N} \\
&= -N \sum_{i=1}^L p_i \log p_i = N \cdot S(p_1, p_2, \cdots, p_L) \quad (17)
\end{aligned}$$

where $S(p_1, p_2, \cdots, p_L) = - \sum_{i=1}^L p_i \log p_i$ is the *Shannon entropy* of the probability distribution $(p_1, p_2, \cdots, p_L)$.

In Rock Physics we frequently have to solve an *overdetermined* system of equations

$$\left. \begin{aligned} F_1(\xi_1, \xi_2, \cdots, \xi_L) &= y_{\text{measured}}^{(1)} \\ &\vdots \\ F_M(\xi_1, \xi_2, \cdots, \xi_L) &= y_{\text{measured}}^{(M)} \end{aligned} \right\} (L \gg M)$$

In the *Maximum Entropy (ME) Technique* we accept that particular solution of this system whose *Shannon entropy* is *maximal*.

Maximum Entropy (ME) Pore Shape Inversion

In an ME-based *rock-physical inversion* Doyen (1987) determined the *pore-shape distribution* in igneous rocks from hydraulic conductivity and/or dc electric conductivity measurements performed at a series of confining pressures. His rock model consisted of a random distribution of spherical pores connected with each other by tubes (“throats”). (This model is discussed in Korvin et al. 2014.)

At a given reference pressure $P = P_0$ the pores’ radii r are distributed according to the probability density function (*pdf*) $n(r)$; the throat-length l is distributed according to the *pdf* $n(l)$; the throats have elliptic cross-section with semi-axes b and c following the bivariate *pdf* $n(\alpha, c)$ where α is the aspect ratio $\alpha = b/c$. Using *Elasticity Theory* (Zimmerman 1991) to compute the deformation of voids under pressure P , the *pdf*’s for $r(P)$, $c(P)$, $l(P)$, $\alpha(P)$ can be determined for any pressure step from their values at reference pressure. The *pdf* $n(\alpha, c)$ satisfies the *self-consistency* equation (cf. Kirkpatrick 1973; see section “*Effective Medium (EM) Approximation*”) for all pressure steps P :

$$\sum_{\alpha, c} n(\alpha, c) \frac{g_e^*(P) - g_e(P, \alpha, c, l)}{g_e(P, \alpha, c, l) + \left(\frac{Z}{2} - 1\right) g_e^*(P)} \quad (18a)$$

$$\sum_{\alpha, c} n(\alpha, c) \frac{g_h^*(P) - g_h(P, \alpha, c, l)}{g_h(P, \alpha, c, l) + \left(\frac{Z}{2} - 1\right) g_h^*(P)} = 0 \quad (18b)$$

where Z is the average pore coordination number (number of throats incident to a pore); $g_e^*(P)$ and $g_h^*(P)$ are the measured bulk electric and hydraulic conductivities at pressure P , and $g_e = g_e(P, \alpha, c, l)$ and $g_h = g_h(P, \alpha, c, l)$ are the theoretical conductivities of an originally (α, c) -shaped throat of length l subjected to pressure P .

Elasticity Theory also provides a theoretical value $\beta_p(r, \Phi)$ for the compressibility of a rock at pressure P if it contains a volume-fraction Φ of r -sized pores; and an expression for its expected value $\beta_p(\{n(r)\}, \Phi)$. Similarly, for a volume fraction Φ of throats of length l and cross-sectional shape (α, c) both $\beta_p(\alpha, c, l, \Phi)$ and its expected value can be theoretically determined.

Subjecting the rock to pressure P , the pore parameters change as $r \rightarrow r(P)$, $l \rightarrow l(P)$, $c \rightarrow c(P)$, $\alpha \rightarrow \alpha(P)$, the measured bulk compressibility becomes $\beta(P)$. Assuming that the compressibilities due to pores and throats are independent and additive, one gets

$$\beta_p(\{n(r)\}, \Phi_p, P) + \beta_t(\{n(\alpha, c)\}, \Phi_t, l, P) = \beta(P) \quad (19)$$

Let $V(r)$ be the volume of a pore of radius r , and $V(\alpha, c, l)$ the volume of an (α, c) -shaped tube of length l . Then $n(r)$ and $n(\alpha, c)$ satisfy the additional constraints:

$$\begin{aligned}
\Sigma_r n(r) &= 1, \Sigma_{\alpha, c} n(\alpha, c) \\
&= 1, N_p \Sigma_r n(r) V(r) + N_t \Sigma_{\alpha, c} n(\alpha, c) V(\alpha, c, l) \\
&= \Phi_p + \Phi_t = \Phi
\end{aligned}$$

where N_p and $N_t = N_p \frac{Z}{2}$ are the numbers of pores, respectively throats, in a unit volume of rock. By simple geometry, $N_p, N_t, \Phi_p, \Phi_t, Z, l$ can be expressed in terms of $n(r), n(\alpha, c), \Phi$. As there are much more possible values of $n(r)$ and $n(\alpha, c)$ than pressure steps P , we assume that $n(r)$ and $n(\alpha, c)$ are *Maximum Entropy* solutions, that is,

$$\begin{aligned}
-\Sigma_r n(r) \log n(r) &= \max; \quad -\Sigma_r n(\alpha, c) \log n(\alpha, c) = \max \\
-\Sigma_r n(r) \log n(r) &= \max; \quad -\sum_{\alpha, c} n(\alpha, c) \log n(\alpha, c) = \max
\end{aligned} \quad (20)$$

subject to the conditions

$$\sum_{\alpha, c} n(\alpha, c) \frac{g_e^*(P) - g_e(P, \alpha, c, l)}{g_e(P, \alpha, c, l) + \left(\frac{Z}{2} - 1\right) g_e^*(P)} = 0 \quad (20a)$$

$$\sum_{\alpha, c} n(\alpha, c) \frac{g_h^*(P) - g_h(P, \alpha, c, l)}{g_h(P, \alpha, c, l) + \left(\frac{Z}{2} - 1\right) g_h^*(P)} \quad (20b)$$

$$\beta_p(\{n(r)\}, \Phi_p, P) + \beta_l(\{n(\alpha, c)\}, \Phi_l, l, P) = \beta(P) \quad (20c)$$

$$\sum_r n(r) = 1, \sum_{\alpha, c} n(\alpha, c) = 1,$$

$$N_p \sum_r n(r) V(r) + N_l \sum_{\alpha, c} n(\alpha, c) V(\alpha, c, l) = \Phi_p + \Phi_l = \Phi \quad (20d)$$

The constraining Equations (20a–d) have the common form

$$\sum_{r, \alpha, c} n(r, \alpha, c) A(r, \alpha, c, P) = 0 \text{ for } P = P_1, P_2, \dots, P_N \quad (21)$$

where (r, α, c) , satisfying $n(r, \alpha, c) \geq 0$; $\sum_{r, \alpha, c} n(r, \alpha, c) = 1$ is the joint *pdf* of $\{r, \alpha, c\}$ at the reference pressure. Its *Shannon entropy* is

$$S[n(r, \alpha, c)] = - \sum_{r, \alpha, c} n(r, \alpha, c) \log n(r, \alpha, c) \quad (22)$$

Using the Lagrange multiplier technique, we first find the vector which minimizes the function

$$f(\lambda_{P_1}, \dots, \lambda_{P_N}) = \log \left[\sum_{r, \alpha, c} \exp \left\{ - \sum_{k=1}^N \lambda_{P_k} A(r, \alpha, c, P_k) \right\} \right] \quad (23)$$

and then find the ME solution (called “pore spectra”) as

$$n(r, \alpha, c) = \frac{\exp \left\{ - \sum_{k=1}^N \lambda_{P_k} A(r, \alpha, c, P_k) \right\}}{\sum_{r, \alpha, c} \exp \left\{ - \sum_{k=1}^N \lambda_{P_k} A(r, \alpha, c, P_k) \right\}} \quad (24)$$

Shale Compaction and Maximal Entropy

By Athy’s law (Athy 1930) in thick pure shale porosity decreases with depth as

$$\Phi(z) = \Phi_0 \exp(-kz) \quad (25)$$

where $\Phi(z)$ is porosity at depth z , Φ_0 porosity at the surface, and k a constant. Assuming all pores have the same volume, the porosity of a rock is proportional to the number of pores in

a unit volume of the rock. Athy’s rule states in this case that the pores in compacted shales are distributed in such a manner that their number in a unit volume of rock exponentially decreases with depth. There are several analogies of this rule in Statistical Physics. The most familiar is the *barometric equation* of Boltzmann for the density $\rho(z)$ of the air at altitude z as $n\rho(z) = \rho(0) \cdot \exp\left[-\frac{mgz}{kT}\right]$, where m is the mass of a single gas molecule, g gravity acceleration, k Boltzmann’s constant, and T absolute temperature. In Statistical Physics (Landau and Lifshitz 1980: 106–114) Boltzmann’s equation is derived from the assumptions that the gas particles move independently of each other and the system tends toward its most probable (*maximum entropy*) state.

During compaction of shale, water is expelled and clay particles rearrange themselves toward a more dense system of packing. Korvin (1984) adopted Litwiniszyn’s model (1974) and considered shale compaction history as an *upward migration of pores*. Take a rectangular prism P of the present-day shale of unit cross-section reaching down to the basement at depth Z_0 , and suppose its *mean porosity* is Φ , that is, it contains a fractional volume ΦZ_0 of fluid and a volume $(1 - \Phi)Z_0$ of solid clay particles. Assume that the compaction process is *ergodic*, that is, it tends toward the *maximum-entropy final state*. Neglecting the actual depositional history we assume for time $t = 0$ an initial condition where a prism of water of unit cross-section, height ΦZ_0 and density ρ_1 had been overlain by solid clay of height $(1 - \Phi)Z_0$ and density ρ_2 , $\rho_1 < \rho_2$. Divide the prism of water into $\mathfrak{N}$ “particles” (water-filled pores), each of volume ΔV , which at $t = 0$ started to migrate upwards independently of each other, until the final (*maximum entropy*) state had been reached. The initial potential energy of the system had been

$$E = \mathfrak{N} \cdot V \cdot g(\rho_2 - \rho_1)(1 - \Phi)Z_0, \quad (26)$$

where initial porosity and particle number are connected by $\mathfrak{N} = \frac{Z_0 \Phi}{\Delta V}$. Divide the prism P into N equal slabs of thickness $\Delta z = Z_0/\Delta z$, denote the i th slab by γ_i ($i = 0, 1, \dots, N - 1$), and divide the prism P into $N^* = Z_0/\Delta V$ nonoverlapping small cubes. We have $\mathfrak{N} \ll N^*$ if Φ is sufficiently small. We rank the N^* possible positions, called “states,” of a pore into N groups: a pore is said to belong to the group γ_i if and only if its center (x, y, z) lies within the slab γ_i . This implies every group γ_i contains $G = \Delta z/\Delta V$ states. Suppose that N_i pores are found in state γ_i . The numbers N_i satisfy two constraints, the *conservation of pore-particle number*, and the *conservation of total potential energy*:

$$\sum_{i=0}^{N-1} N_i = \mathfrak{N} \quad (27a)$$

$$\sum_{i=0}^{N-1} \varepsilon_i N_i = E \quad (27b)$$

where E is the total energy (see Eq. 26); ε_i is the potential energy of a single pore particle in group γ_i , due to buoyancy:

$$\varepsilon_i = g(\rho_2 - \rho_1) \cdot \Delta V \cdot i \cdot \Delta z \quad (28)$$

The set of numbers $\{N_i\}$ determine the *macroscopic* distribution of pores inside the prism P . Apart from a constant factor, the entropy of the distribution is

$$S = \sum_{i=1}^{N-1} N_i \log \frac{eG}{N_i} \quad (29)$$

Denote the average number of pore particles in group γ_i by $\bar{n}_i$, then $\bar{n}_i = N_i/G$,

$$S = G \sum_{i=1}^{N-1} \bar{n}_i \log \frac{e}{\bar{n}_i} \quad (30)$$

and the constraints (27a, b) become

$$G \cdot \sum_{i=0}^{N-1} \bar{n}_i = \mathfrak{N}, \quad G \cdot \sum_{i=0}^{N-1} \bar{n}_i \varepsilon_i = E \quad (31)$$

The pore particles will migrate to a position such that the entropy (Eq. 29) be maximal. To maximize the entropy subject to the constraints (31), we introduce Lagrange multipliers α, β assume that

$$\frac{\partial}{\partial \bar{n}_i} (S + \alpha \frac{\mathfrak{N}}{G} + \beta \frac{E}{G}) = 0 \quad (i = 0, 1, \dots, N-1), \text{ that is}$$

$$\bar{n}_i = \exp(\alpha + \beta \varepsilon_i), \text{ wherefrom } \exp \alpha = \frac{\Phi}{1-\phi}, \beta = -\frac{1}{E} \text{ and}$$

$$\Phi(z) = \frac{\Phi}{1-\phi} \cdot \exp \left[-\frac{z}{(1-\phi)Z_0} \right] \quad (32)$$

Identifying the first factor in Eq. (32) with surface porosity Φ_0 , the equation becomes

$$\Phi(z) = \Phi_0 \cdot \exp \left[-\frac{(1+\Phi_0)z}{Z_0} \right] \quad (33)$$

an equation that reproduces Athy's compaction law.

Contact Force Distribution in Granular Media

K. Bagi (2003) determined the probability density functions of contact force components in the principal directions of average stress in random granular assemblies by maximizing the statistical entropy, and proved that the distribution of force magnitudes is exponential. She considered a body consisting of randomly packed, cohesionless grains. If external stresses

are acting on this body's boundary, contact forces arise between neighboring grains and the average stress of the assembly, $\bar{\sigma}_{ij}$, depends on the contact forces f_i^c between neighbor grains and on the vectors l_i^c pointing from the center of the first grain to the center of the second,

$$\bar{\sigma}_{ij} = \frac{1}{V} \sum_{c=1}^M l_i^c f_j^c \quad (34)$$

(M is the total number of contacts; the index “ c ” runs over all contacts; $i, j = 1, 2, 3$ indicate vector components; V is the total volume). If the coordinate axes (x_1, x_2, x_3) are parallel to the principal directions of $\bar{\sigma}_{ij}$, then $\bar{\sigma}_{ij} = 0$ if $i \neq j$. Consider Eq. (34) first for $i = j = 1$:

$$\bar{\sigma}_{11} = \frac{1}{V} \sum_{c=1}^M l_1^c f_1^c. \quad (35)$$

Since when two grains are in contact, any of them can be “first” or “second,” we can assume that $0 \leq f_1^c \leq f_{\max}$. We discretize this domain into equal (small) intervals: a particular f_1^c can fall into the k th interval where the medium value is F_{1k} with probability $p_k^{(1)}$, $k = 1, 2, \dots$, or into the second interval where the medium value is F_{12} , etc. The distribution of the f_1 -component is described by $p_1^{(1)}, p_2^{(1)}, \dots, p_k^{(1)}, \dots$; representing the probabilities that f_1^c falls into the 1st, 2nd, ... k th, ... interval. Next consider all those grain contacts where the f_1^c contact force component falls into a chosen k th interval (that is $f_1^c \approx F_{1k}$). Take the average of the l_1^c grain-center-to-grain-center vector components for these contacts, and denote it as $\bar{l}_{1k}^{(1)}$ where the superscript “(1)” expresses that the grouping was done according to the f_1 -components.

With these notations, Eq. (35) is averaged to

$$\bar{\sigma}_{11} = \frac{1}{V} \sum_{k=1}^{\infty} (M \cdot p_k^{(1)}) \bar{l}_{1k}^{(1)} F_{1k}. \quad (36)$$

and we similarly get all nine equations

$$\bar{\sigma}_{ij} = \frac{1}{V} \sum_{k=1}^{\infty} (M \cdot p_k^{(j)}) \bar{l}_{ik}^{(j)} F_{jk} \quad (37)$$

Suppose the geometrical data and average stress are given and we are searching for the *distribution* of the i th contact force component $\{f_i\}$. The unknown $\{p_1, p_2, \dots, p_k, \dots\}$ values satisfy

$$\sum_{k=1}^{\infty} p_k = 1 \quad (38)$$

and (for a fixed $i = j$)

$$\bar{\sigma}_{ij} = \frac{M}{V} \sum_{k=1}^{\infty} p_k \bar{l}_{ik}^{(j)} F_{jk}. \quad (39)$$

We need a geometric assumption on the $\bar{l}_{ik}^{(j)}$ values. Suppose that they are constant:

$$\bar{l}_{i1}^{(j)} = \bar{l}_{i2}^{(j)} = \bar{l}_{i3}^{(j)} = \dots = \bar{l}_i^{(j)} \quad (40)$$

The average stress then can be expressed (for fixed $i = j$) as

$$\bar{\sigma}_{ij} = \frac{M}{V} \bar{l}_i \sum_{k=1}^{\infty} p_k F_{jk}. \quad (41)$$

We are looking for that distribution which has the highest entropy:

$$-\sum_{k=1}^{\infty} p_k \log p_k = \max, \quad (42)$$

subject to the conditions

$$\sum_{k=1}^{\infty} p_k = 1 \quad (43)$$

$$\bar{\sigma}_{ij} = \frac{M}{V} \sum_{k=1}^{\infty} p_k \bar{l}_{ik}^{(j)} F_{jk} \text{ (for a fixed } i = j). \quad (44)$$

Introduce the Lagrange-multipliers α and β associated with the constraints (Eqs. 43 and 44). Easy algebra yields:

$$p_k = \frac{1}{\exp(1 + \alpha)} \cdot \exp(-\beta \bar{l}_i^{(j)} F_{jk}) \quad (45)$$

where α and β can be (numerically) determined from the system of nonlinear equations (using the given data $\bar{\sigma}_{ii}$, $\bar{l}_i$, V and M):

$$\sum_{k=1}^{\infty} F_{jk} \exp(-1 - \beta \bar{l}_i^{(j)} F_{jk} - \alpha) - \frac{V}{M \bar{l}_i^{(j)}} \bar{\sigma}_{ij} = 0 \text{ (} i = j) \quad (46)$$

$$\sum_{k=1}^{\infty} \exp(-1 - \beta \bar{l}_i^{(j)} F_{jk} - \alpha) - 1 = 0 \quad (47)$$

Equation (45) means that the *distribution of contact force components is exponential*, provided that Eq. (40) is an acceptable simplification.

Self-Consistency and Effective Media

Effective Medium (EM) Approximation

A good introduction (Kirkpatrick 1973) to classical *Effective Medium Theory* is the study of random resistors on the bounds

of a lattice. Apply an external field along one axis so that the voltages increase by a constant amount per row of nodes. The average effect of the random resistors can be described by an *effective medium*, that is, a hypothetical homogeneous medium in which the total field inside is equal to the external field. Consider an effective field which is made up of equal conductances, g_m , connecting nearest neighbors on a cubic mesh. To find g_m , we require that the local perturbations in this medium due to the voltages, induced when individual conductances g_{ij} replace g_m , should average to zero. Consider a conductance g_{AB} between randomly picked neighboring nodes A , B in the direction of the external field. Using Kirchhoff's laws it can be shown that if we change g_m to g_{AB} , the arising voltage, V_o , induced between A and B will be

$V_o = V_m(g_m - g_{AB}) / [g_{AB} + (\frac{Z}{2} - 1)g_m]$, where V_m is the constant increase in voltages per row, and Z is the coordination number.

If the conductivities g_{ij} are distributed according to the *pdf* $f(g)$, the requirement that the average of V_o should vanish yields an equation for g_m :

$\int dg f(g)(g_m - g) / [g + (\frac{Z}{2} - 1)g_m]$. (A special case of this equation was applied in section “[Maximum Entropy \(ME\) Pore Shape Inversion](#)”, as Eq. 18a, 18b.)

Another simple case of the *EM* approximation (Stroud 1998) concerns the random mixture of two types of grains, denoted by 1 and 2, which are present in relative volume fractions p and $1 - p$, and characterized by conductivities σ_1 and σ_2 . To calculate the effective conductivity σ_e of this composite, imagine that each grain, instead of being embedded in its actual random environment, lies in an homogeneous *effective medium*, whose conductivity σ_e will be determined *self-consistently*. If the grains are spherical, the electric field inside them is given in Electrostatics as $E_i = E_0 \frac{3\sigma_e}{\sigma_i + 2\sigma_e}$ ($i = 1$ or $i = 2$), where E_0 is the electric field far from the grain. *Self-consistency* requires that the *average electric field* within the grain should equal E_0 , that is

$p E_0 \frac{3\sigma_e}{\sigma_1 + 2\sigma_e} + (1 - p) E_0 \frac{3\sigma_e}{\sigma_2 + 2\sigma_e} = E_0$ leading to the quadratic equation

$p \frac{\sigma_1 - \sigma_e}{\sigma_1 + 2\sigma_e} + (1 - p) \frac{\sigma_2 - \sigma_e}{\sigma_2 + 2\sigma_e} = 0$. The equation has two solutions for σ_e , one physically sensible, the other unphysical.

The *EM* approximation is also used in Percolation Theory (see section “[Percolation Theory](#)”) where transport properties (such as conductivity or diffusivity) grow as a power-function above, but near to, the percolation threshold, p_c . For $p > p_c$ the electrical conductivity σ of a random network grows as $\sigma \propto (p - p_c)^t$, $p > p_c$ where p is the occupation probability for a site or bond, and the scaling exponent t is equal to 2 in 3D. In the *Effective Medium (EM)* approach (Ghanbarian et al. 2014) a randomly selected part of the heterogeneous medium is replaced by the homogeneous material. Replacing the actual transport coefficient (e.g., conductivity) by an *effective* one perturbs the local current. The effective conductivity is determined by requiring that the average of these

perturbations be zero. For the lattice percolation model of electric conductivity in rocks this gives (for two components, see Kirkpatrick 1973, Stroud 1998) $\sigma(p)/\sigma_b = 1 - \frac{1-p}{1-Z}$ where σ_b is the electrical conductivity of the brine, grains are nonconducting, and Z is the coordination number. In n -dimensional lattices the coordination number Z and p_c are approximately related as $Zp_c = d/(d-1)$ so in 2D one has $2/Z \approx p_c$, and $\frac{\sigma(p)}{\sigma_b} \approx \frac{p-p_c}{1-p_c}$.

Differential Effective Medium (DEM) Approximation

The elastic properties of porous or cracked rocks are commonly modeled by the *DEM* (Differential Effective Medium) approach (Mavko et al. 1998; Almquist et al. 2011; Haidar et al. 2018). In *DEM* a composite material is constructed step-wise by making infinitesimal changes to an already existing composite. For example, a two-phase porous or cracked rock can be built up by incrementally adding small fractions of pores or cracks to the rock matrix. As we insert new inclusions into the background model, it will continuously change as:

$$\begin{aligned} (1 - \Phi)[K^*(\Phi)] &= (K_2 - K^*)P^{(*)2}(\Phi) \\ (1 - \Phi)[\mu^*(\Phi)] &= (\mu_2 - \mu^*)Q^{(*)2}(\Phi) \end{aligned}$$

(see Mavko et al. 1998) where Φ is porosity; $K^*(\Phi)$ is the effective bulk moduli of DEM; K^* is bulk modulus of the matrix (phase 1); K_2 bulk modulus of the inclusion (phase 2); $P^{(*)2}$ is geometry factor for an inclusion of material 2 in a background medium with effective moduli K^* and μ^* ; $\mu^*(\Phi)$ is the effective shear moduli of DEM; μ^* shear modulus of the matrix (phase 1); μ_2 shear modulus of the inclusion (phase 2); $Q^{(*)2}$ geometry factor for an inclusion of material 2 in a background medium with effective moduli K^* and μ^* . The DEM equations (for K and μ) are coupled, as both depend on both the bulk and shear moduli of the composite through the geometry factors. The equations are numerically integrated starting from porosity $\Phi = 0$ with initial values $K^*(0) = K_m$ and $\mu^*(0) = \mu_m$ which are the mineral values for the single homogeneous solid constituent. Integration then proceeds from $y = 0$ to the desired highest value $y = \Phi_{\max}$ as the inclusions are slowly introduced into the solid. The method needs a background rock matrix, the geometry factors, the elastic moduli of the inclusions, and the fraction of inclusions as input. The value of the aspect ratios are also needed in the geometry factors. There are three ranges of aspect ratio values, for the interparticle pores, the stiff pores, and the cracks. There is a control step where one calculates the reference velocity V_p^{ref} using the DEM equations. (It depends on the aspect ratio of the interparticle pores, the fraction of inclusions, the elastic moduli of the rock matrix and of the inclusions.) The reference value V_p^{ref} serves to decide whether stiff pores or cracks are to be added to the rock matrix. If

$V_p^{\text{ref}} < V_p^{\text{meas}}$, then stiff pores are added, and if $V_p^{\text{ref}} > V_p^{\text{meas}}$, then cracks are added to the matrix. When the process is complete, the effective elastic moduli can be calculated.

In an interesting application (Almquist et al. 2011) of *DEM* to compute the elastic constants for calcite and muscovite mixtures the background medium was *anisotropic*. For anisotropic elastic media *DEM* is computed as

$$\frac{dC^{\text{DEM}}}{dV} = \frac{1}{1-V} (C_i - C^{\text{DEM}}) A_i$$

where C^{DEM} is the elastic tensor of the effective media, V is the volume fraction of the inclusions, C_i is the elastic tensor of the inclusion, and A_i , which relates the strain inside the inclusion with that of the background matrix, is defined as

$$A_i = [I + G(C_i - C^{\text{DEM}})]^{-1}$$

Here I is the fourth-rank unit tensor, G is a symmetric tensor Green's function, C_i is the elastic modulus of the inclusion, the tensor C^{DEM} is updated in each inclusion step. Inclusions are ellipsoids with given aspect ratio ($a \geq b \geq c$).

Thermodynamic Algorithms

Random Walk

Gaussian random walk is a mathematical model of the *Brownian motion* of small particles in liquids. For this motion the change of the position $X(t)$ of the randomly moving particle $\Delta X(t) = X(t + \Delta t) - X(t)$ obeys a Gaussian distribution with mean $\langle \Delta X(t) \rangle = 0$ and variance $\langle [\Delta X(t)]^2 \rangle^{1/2} \propto \Delta t$. Two characteristic rock-physical applications of random walk modeling are a study of nuclear magnetic relaxation (NMR) in brine-filled porous rocks (Jin et al. 2009), and random-walk-based determination of the electric conductivity in rocks (Ioannidis et al. 1997).

The *random-walk method* of simulating the *Nuclear Magnetic Resonance* (NMR) response of fluids in porous rocks can be applied on *grain-based* and *voxel-based representations* of the rock. In the grain-based approach a spherical grain pack is the input, where the solid surface is analytically defined; in the voxel-based approach the input is a computer-generated 3D image of the reconstructed porous media. The implementation of random walk is the same in both cases, but it has been found that spin magnetization decays much faster in the digitized models than in case of analytically given surfaces because of overestimating the irregular pore surface areas.

For fluids in porous media, total magnetization originates from diffusion and relaxation processes. Three processes are involved in the relaxation of spin magnetization (only

transverse relaxation is considered): (1) bulk fluid relaxation, with characteristic time T_{2B} due to dipole–dipole interactions between spins within the fluid; (2) surface relaxation, characterized by effective relaxation time T_{2S} , due to the additional interaction of protons at the pore-grain interface with paramagnetic impurities in the grains, and the motion of water molecules in a layer near the pore-grain interface; and (3) relaxation due to background magnetic field heterogeneities, T_{2D} . The effect of the pore surface on the relaxation time T_{2S} is proportional to specific surface area: $\frac{1}{T_{2S}} = \rho \frac{S}{V}$ where ρ is surface relaxivity, D_B diffusion coefficient of the bulk fluid, S is pore surface area, and V pore volume. The decay rate T_2 of the magnetization is given by $\frac{1}{T_2} = \frac{1}{T_{2B}} + \frac{1}{T_{2S}}$. Far away from a boundary, T_2 is equal to the bulk fluid transversal relaxation time, T_{2B} . For spins close to a pore boundary, the magnetization decay is locally enhanced by surface relaxation. Most random-walk simulations of NMR assume that the spin is “killed” with a probability p when it reaches a boundary, and relate this probability to surface relaxivity ρ as $p = 0.96A \frac{\rho \Delta r}{D_B}$ where Δr is the displacement the spin achieves during the interval $[t, t + \Delta t]$ when it reaches the boundary, and A is an empirical factor of order 1 (usually set to 2/3). In the discussed more realistic model (Jin et al. 2009) of local surface relaxation the spin is not “killed,” but its magnetization decreases by a factor $(1 - p) \approx \exp[-\Delta t(p/\Delta t)]$. Therefore, the total relaxation rate becomes $1/T_2 = 1/T_{2B} + p/\Delta t$. Equivalently, the relaxation time used in each step of the random walk can be written

$$\frac{1}{T_2} = \frac{1}{T_{2B}} + \chi \frac{3.84\rho}{\Delta r} \quad (48)$$

where in the grain-based model, $\chi = 1$ when the walker is located within a step of the relaxing boundary, and 0 otherwise.

The starting points of walkers are randomly picked in the pore-space occupied by fluids (water and/or oil). Each walker is allowed to walk for a sufficiently long time, whenever it attempts to step out of the pore space into the matrix, its magnetization decays with a rate determined by Eq. (48). At each time-step Δt , a random vector $\vec{n} = (n_x, n_y, n_z)$ is generated, whose independent components are normally distributed with unit variance and zero mean. The walker is then spatially displaced by $\Delta \vec{r} = \sqrt{(6D_B \Delta t)} \frac{\vec{n}}{\|\vec{n}\|}$. The time step Δt is dynamically changed along the walk so that it is smaller than any magnetic-field pulse duration, and the amplitude of the total displacement, $\Delta \vec{r}$, is much shorter than the relevant geometric length scales (e.g., pore throats, wetting film thickness, etc.). It was assumed that the pores are fully brine-saturated, the pulse sequence was of the Carr–Purcell–Meiboom–Gill (CPMG) type with an inter-echo spacing of 1 ms, the parameters were $T_{2B} = 2800\text{ms}$, $D_B = 2\mu\text{m}^2/\text{ms}$,

$\rho = 0.005$. One analytically treatable case, a cubic packing of spheres, a random packing of monodisperse and polydisperse spheres, and a digitized micro X-ray-CT image were used as test cases. The theoretical case was a single spherical pore of radius R where the magnetization decay in the fast diffusion limit ($\rho R/D_B < 1$) is given by $\frac{M(t)}{M_0} = \exp\left[-t\left(\frac{1}{T_{2B}} + \rho \frac{S}{V}\right)\right]$, M_0 being the initial transverse magnetization (equal to 1 in this study). Simulations were performed for the case $\frac{\rho R}{D_B} = 0.02$. Grain-pack based simulations were made for the cubic packing of spheres, and for random packing of monodisperse and polydisperse spheres. The voxel-based approach was run on the micro X-ray-CT image of a Fontainebleau sandstone sample with 21.5% porosity, and the image consisted of $512 \times 512 \times 512$ voxels, with $5.68 \mu\text{m}$ voxel size.

In another random-walk model (Ioannidis et al. 1997), in an attempt to find the formation factor F in Archie’s equation, instead of solving Laplace’s equation these authors exploited the formal analogy between random walks and the solutions of the Laplace equation (Kim and Torquato 1990). They calculated the mean square displacement a function of time for a large number of random walkers. A single walker starts at a random void voxel (i_0, j_0, k_0) . It can take random steps to any neighboring void, without penetrating solid grains. The time required for each step is, by Einstein’s rule $t_{v-v} = \frac{(\partial D)^2}{\sigma_0}$, where σ_0 is conductivity of the pore fluid (set to 1), ∂D is distance traveled in one step in a 3D lattice of spacing δ , so that it can be δ , $\delta\sqrt{2}$ or $\delta\sqrt{3}$. To avoid premature disappearance of walkers, periodic boundary conditions are assumed. The random walker travels a large number of steps ($\sim 10^6$) and there are many ($\sim 10^3$) independent walkers. The average displacement after time t will be $\langle R^2 \rangle = \left(\frac{\sigma}{\Phi_a}\right)t$ where $\sigma (= \sigma_0/F)$ is the effective electrical conductivity, and Φ_a is the fraction of voxels accessible for the walker. For such rocks (carbonates, shales) where solid-void, void-solid, and solid-solid transitions are also allowed, Einstein’s formula changes to $t_{s-s} = \frac{(\partial D)^2}{\sigma_s} = \frac{(\partial D)^2}{\sigma_0} F_s$ (F_s is the formation factor of the matrix). Steps between solid and void are only allowed with a given probability. In the model they used $p_{v-s} = \frac{1}{1+F_s}$ and $p_{s-v} = \frac{F_s}{1+F_s}$. The time to cross an interface is $\tau = \left(\frac{2}{1+F_s}\right) \cdot \frac{(\partial D)^2}{4\sigma_0} F_s$, and $t_{s-v} = \frac{t_{s-s}}{4} + \tau$, $t_{v-s} = \frac{t_{v-v}}{4} + \tau$.

Lattice Boltzmann Methods for Flow in Porous Media

The *Lattice Boltzmann Method (LBM)* is a numerical tool for simulating complex fluid flows or other transport processes (Ghassemi and Pak 2010), a *finite-difference method* to solve the *Boltzmann transport equation* on a lattice. It is a simplified *molecular dynamics model* where space, time, and particle-velocities assume discrete values, each lattice node is connected to its neighbors, there can be either 0 or 1 particles at a lattice node, particles move with a given velocity. In

discrete time instants, each particle moves to a neighboring node, and this process is called *streaming*. When more than one particle arrive at the same node from different directions, they *collide* and change their velocities according to *collision rules* conserving particle number (mass), momentum, and energy before and after the collision.

The LBM originated from Boltzmann's kinetic theory of gases, where the gas consists of a large number of particles in random motion. Transport in this model is described by the equation $\frac{\partial f}{\partial t} + \vec{u} \cdot \nabla f = \Omega$ where $f(\vec{x}, t)$ is the particle distribution function, $\vec{u}$ is particle velocity, Ω the collision operator. As compared to Boltzmann's gas dynamics the number of particles is much reduced, and they are confined to the nodes of a lattice. The different numerical realizations of LBM are classified by the $D_n Q_m$ scheme, where “ D_n ” stands for “ n dimensions,” “ Q_m ” stands for “ m speeds.” Here we only discuss $D_2 Q_9$, the 2D model where a particle moves (“streams”) in nine possible directions, including the possibility to stay at rest. These velocities are referred to as *microscopic velocities* and are denoted by e_i , $i = 0, \dots, 8$. In the $D_2 Q_9$ model the nine velocity vectors are:

i	0	1	2	3	4	5	6	7	8
$\vec{e}_i$	(0,0)	(1,0)	(0,1)	(-1,0)	(0,-1)	(1,1)	(-1,1)	(-1,-1)	(1,-1)

Each particle follows a discrete distribution of probabilities $f_i(\vec{x}, t)$, $i = 0 \dots 8$, of streaming in any one particular direction. The *macroscopic fluid density* is the sum of microscopic particle distribution functions, $\rho(\vec{x}, t) = \sum_{i=0}^8 f_i(\vec{x}, t)$, the *macroscopic velocity* $\vec{u}(\vec{x}, t)$ is the average of microscopic velocities $\vec{e}_i$ weighted with the distribution functions f_i , $\vec{u}(\vec{x}, t) = \frac{1}{\rho} \sum_{i=0}^8 c f_i \vec{e}_i$ where $c = \Delta x / \Delta t$ is the lattice speed.

The key steps in LBM are *streaming* and *collision*, which are given by

$$\begin{cases} f_i(\vec{x} + c \vec{e}_i \Delta t, t + \Delta t) - f_i(\vec{x}, t) & \text{(streaming)} \\ -\frac{[f_i(\vec{x}, t) - f_i^{eq}(\vec{x}, t)]}{\tau} & \text{(collision)} \end{cases}$$

where $f_i^{eq}(\vec{x}, t)$ is the *local equilibrium distribution*, and τ the relaxation time toward local equilibrium. For single-phase flows, it suffices to use the simplified Bhatnagar-Gross-Krook collision rules (Bhatnagar et al. 1954) where equilibrium distribution is defined as $f_i^{eq}(\vec{x}, t) = w_i \rho + \rho s_i(\vec{u}(\vec{x}, t))$

with $s_i(\vec{u}) = w_i \left[3 \frac{\vec{e}_i \cdot \vec{u}}{c} + \frac{9}{2} \frac{(\vec{e}_i \cdot \vec{u})^2}{c^2} - \frac{3}{2} \frac{\vec{u} \cdot \vec{u}}{c^2} \right]$ and the weights w_i are 4/9 for $i = 0$; 1/9 for $i = 1, 2, 3, 4$; and 1/36 for $i = 5, 6, 7, 8$. The fluid's kinematic viscosity in the $D_2 Q_9$

model is related to relaxation time by $\nu = \frac{2\tau-1}{6} \cdot \frac{(c\Delta x)^2}{\Delta t}$. Parameters are selected such that the lattice speed c be much larger than the maximum fluid velocity v_{max} expected to arise in the simulation. This is expressed by the “computational” *Mach number*, $Ma = v_{max}/c$. Theoretically, it is required that $Ma \ll 1$, in practice, Ma should be, at least, ≤ 0.1 .

The algorithm runs as follows: (1) Initialize $\rho, \vec{u}, f_i$ and f_i^{eq} ; (2) Streaming step: $f_i \rightarrow f_i^*$ in the direction of $\vec{e}_i$; (3) Compute the macroscopic ρ and $\vec{u}$ from f_i^* ; (4) Compute f_i^{eq} ; (5) Collision step: calculate the updated distribution $f_i = f_i^* - \frac{1}{\tau}(f_i^* - f_i^{eq})$; (6) Repeat steps 2–5.

During streaming and collision, the boundary nodes need special treatment. In classical fluid dynamics, the interface between solids and the fluid is assumed to be *non-slip*, but this would slow down computations. In most studies “*bounce-back*” conditions are used, so that any flux of fluid particles that hits a boundary simply reverses its velocity.

Simulated Annealing

Simulated Annealing (SA) is an optimization algorithm devised by Kirkpatrick et al. (1983), who realized the analogy between the thermodynamics of the *annealing* of metals (i.e., the metallurgic technology of alternating heating and controlled cooling of a metal to reduce its defects), and the optimization problem of finding the *global minimum* of a multiparameter objective function. In SA a random perturbation is applied to a system's *current configuration*, so that a *trial configuration* is obtained. Let E_c and E_t be the energy levels of the current and trial configurations. If $E_c \geq E_t$, then the trial configuration is accepted and it becomes the current configuration. On the other hand, if $E_c < E_t$, then the trial configuration is accepted with a probability given by $P(\Delta E) = \exp[-\Delta E/k_B T]$ where $\Delta E = E_t - E_c$, k_B is the Boltzmann constant, and T is temperature. This step helps the system to jump out from local minima. After a sufficient number of iterations at a fixed temperature, the system approaches equilibrium, where the free energy reaches its minimum value. By gradually decreasing T and repeating the simulation process (starting out every time from the equilibrium state found for the previous T value), new lower energy configurations are achieved. Two characteristic rock-physical applications (apart from *pore-space reconstruction*, see section “[Reconstructing 3D Pore Space from 2D Sections](#)”) are *determination of fluid distribution in a porous rock* (Politis et al. 2008) and finding the *soil-components' specific thermal conductivity* (Stefaniuk et al. 2016). In the first, pore space is represented by a set of cubic voxels of side l . Each voxel is labeled by an integer indicating its phase. The solid phase is labeled as 0, the fluid phases as 1, 2, 3, $\dots$, n if there are n different pore-fillers. The saturation S_i of phase i is the volume fraction of the total pore space occupied by phase i . The distribution of the n fluid phases in the pore space is

determined assuming that it minimizes the total interfacial free energy

$$G_s = \sum_{i=0}^{n-1} \sum_{j>i}^n A_{ij} \sigma_{ij}, \quad (49)$$

where A_{ij} is the area of the interface between phases i and j , σ_{ij} the interfacial free energy per unit area between phases i , j . The interfacial free energies obey Young's equation so that the following $n(n-1)/2$ equations are satisfied:

$$\sigma_{0i} = \sigma_{ij} \cos \theta_{ij} \quad (50)$$

where θ_{ij} is the contact angle of the ij -interface with the solid surface, $i \neq 0$, $j \neq 0$, $i < j$. Suppose n fluid phases are distributed in the pore space. The number of voxels belonging to each phase depends on the saturation S_i . At each minimization step n voxels, each from a different fluid phase, are randomly selected, and $n(n-1)/2$ random swaps are performed. Each trial swap causes a change of G_s by $\Delta G_{s,ij}$ where $i < j$. If at least one $\Delta G_{s,ij} < 0$, the trial swap with the minimum $\Delta G_{s,ij}$ is accepted. If every $\Delta G_{s,ij} > 0$, the swap $i \leftrightarrow j$ is accepted with probability

$$P_{ij} = \frac{\exp[-\Delta G_{s,ij}/G_{\text{ref}}]}{n(n-1)/2} \quad (51)$$

where G_{ref} stands instead of the $k_B T$ parameter.

After a sufficient number of iterations, the system approaches equilibrium for a specific G_{ref} value. By gradually decreasing G_{ref} , and repeating the process, lower energy levels of G_s will be approached. The "cooling schedule" in this example was $G_{\text{ref}} = \lambda^N G_{\text{ref},N}$ where N is iteration number, λ ($0 < \lambda < 1$) a tunable parameter.

In the *soil-physical* application the soil consists of organic matter, water in its pores, and some soil materials say clay, silt, and sand. Suppose the thermal conductivity of water σ_w and of the organic matter σ_{om} are known, and we want to determine the probability density functions $f_{Cl}(\sigma)$, $f_{Si}(\sigma)$, $f_{Sa}(\sigma)$ for the specific thermal conductivities of the clay, silt, and sand constituents, from the knowledge of the volumetric fractions Φ_{Cl} , Φ_{Si} , Φ_{Sa} , Φ_w , Φ_{om} and from the measured overall thermal conductivity σ^{meas} of the composite soil. The *pdf* of the thermal conductivity of the solid phase is given by the mixture rule (Korvin 1982)

$$f(\sigma) = [\Phi_{Cl} f_{Cl}(\sigma) + \Phi_{Si} f_{Si}(\sigma) + \Phi_{Sa} f_{Sa}(\sigma)] / (\Phi_{Cl} + \Phi_{Si} + \Phi_{Sa}). \quad (52)$$

We create a large cubic sample consisting of $\mathfrak{N} \gg 1$ voxels. Out of them, $\mathfrak{N} \cdot (1 - \Phi_{Cl} - \Phi_{Si} - \Phi_{Sa})$ randomly selected

voxels are kept for water and organic matter, we assign to them the known thermal conductivities $\sigma_w = 0.6 \text{ Wm}^{-1} \text{ K}^{-1}$ and $\sigma_{om} = 0.25 \text{ Wm}^{-1} \text{ K}^{-1}$. The remaining $\mathfrak{N} \cdot (1 - \Phi_w - \Phi_{om})$ voxels are randomly associated with clay, silt, or sand, for example, clay is taken with the probability $\Phi_{Cl} / (\Phi_{Cl} + \Phi_{Si} + \Phi_{Sa})$. The thermal conductivities assigned to these voxels are random values with the pdf (52).

To find the *effective thermal conductivity* σ for a realization ω we numerically solve the heat flow boundary value problem. The solution yields the effective thermal conductivity $\langle \sigma(\omega) \rangle$ and averaging over a sufficient number N of realizations we get the cube's homogenized thermal conductivity as

$$\sigma^{\text{hom}} = \frac{1}{N} \sum_{j=1}^N \langle \sigma(\omega_j) \rangle \quad (53)$$

The *SA* step is used to find such *pdfs* $f_{Cl}(\lambda)$, $f_{Si}(\lambda)$, $f_{Sa}(\lambda)$ for which σ^{hom} of Eq. (53) gives the closest match to the measured data. Starting from some initial guess of the *pdfs* we make them evolve toward optimal solutions that minimize the "energy" E which, at any step, is defined as $E = (\sigma^{\text{hom}} - \sigma^{\text{meas}})^2$. As the *pdf* changes through the steps, it modifies the energy function such that $E \rightarrow E^*$, $\Delta E = E^* - E$. The change of the *pdf* is accepted with the probability $P(\Delta E) = \begin{cases} 1 & \Delta E \leq 0 \\ \exp[-\Delta E/T] & \Delta E > 0 \end{cases}$ where T is a fictitious temperature, being decreased as $T^i = \alpha T^{i-1}$, where $0 < \alpha < 1$ is a control parameter. (In Stefaniuk et al. 2016, they had $\alpha = 0.9$.)

Computational Phase Transitions

Percolation Theory

We explain the method through a hydraulic permeability study (Korvin 1992a; for a percolation treatment of Archie's law of electric conductivity, see, e.g., Hunt 2004). *Percolation Theory* was invented by S. R. Broadbent in the 1950s who worked on the design of gas masks for use in coal mines. The masks contained porous carbon granules into which the gas could penetrate. Broadbent found that if the pores were large enough and sufficiently well connected, the gas could permeate the interior of the granules; but if the pores were too small or inadequately connected, the gas would not get beyond the granules' surface. There was a *critical* porosity and pore interconnectedness, above which the mask worked well and below which it was ineffective. Thresholds of this sort are typical of *percolation processes*. In the bond-percolation problem we assume that a fraction $1-p$ ($0 < p < 1$) of the bonds of a regular grid are randomly cut and a fraction p are left uncut. Then there exists a critical fraction p_c (called *percolation threshold*) such that there is no continuous connection along the bonds of the network between the opposite

Statistical Rock Physics, Table 1 Lattices with their percolation probabilities (From Korvin 1992a, b: 22)

Lattice	Dimension	Coordination n
---------	-----------	----------------

Statistical Rock Physics, Table 2 Tortuosity exponents (after Korvin 1992a, b: 29)

Model of the percolation path	γ	Note
Straight line through the correlation length ξ	0	3D percolation
Minimum path	0.25	3D percolation
Conductive path	0.29	3D percolation-conduction
Self-avoiding random walk on uncut bonds	0.58	3D percolation
Brownian motion in 3D	0.83	
Brownian motion on a d_f -dimensional fractal	$0.83(1.5d_f - 1)$	Using the Alexander-Orbach conjecture

faces for $p < p_c$, and there exists a connection with probability 1 for $p > p_c$. For the two-dimensional square lattice the percolation threshold is 0.5. In the more general case the percolation threshold depends on the dimensionality of the network, d , and on its coordination number Z (the average number of bonds connected to any node of the network), but it is independent of the detailed structure of the network. Table 1 lists coordination numbers and percolation thresholds for some common networks. In n -dimensions, the percolation thresholds and coordination numbers conform closely to the empirical rule: $Zp_c = d/(d - 1)$.

Close to the percolation threshold ($p > p_c$) the nodes that are connected with each other by continuous paths form large clusters of average size ξ , called the *correlation length*. The correlation distance diverges for $p \rightarrow p_c$, $p > p_c$ as $\xi \propto (p - p_c)^{-\nu}$, for three-dimensional networks $\nu = 0.83$, independently of the coordination number. Percolation between two opposite nodes of a cluster, a distance ξ apart, takes place along tortuous zig-zag paths. Near the percolation threshold the length $L(\xi)$ of a typical flow path will grow as a power of ξ : $L(\xi) \propto (p - p_c)^\alpha$ for $p \rightarrow p_c$, $p > p_c$. As the correlation length ξ is the natural length scale in percolation problems, we define the tortuosity of the percolation path as: $\tau = L(\xi)/\xi \propto \xi^{\alpha-1} := (p - p_c)^{-\gamma}$ where, for different models of the percolation path the tortuosity exponents γ are compiled in Table 2.

Percolation theory was applied to compute the permeability of kaolinite-bearing sandstone samples (see Korvin 1992a, b: 28–33. Kaolinite is a “discrete-particle” clay, and it is preferentially deposited in the throats of the sandstone’s pores, completely blocking them.) If the pore structure of a sedimentary rock is converted to a discrete lattice by letting pores correspond to nodes, and throats to bonds, then the continuous Darcy flow becomes a lattice percolation. For kaolinite-bearing sandstones, if a given throat is completely blocked by kaolinite the corresponding bond will be considered as “cut.” If any throat is open with probability p and blocked by kaolinite particles with probability $q = 1 - p$, then in the equivalent lattice

percolation problem a fraction q of the bonds is randomly cut. There exists a *percolation threshold* such that the fluid cannot flow through the sample for $p < p_c$ and percolation starts for $p > p_c$. At the onset of percolation, the fluid particles follow zig-zag paths; the closer p is to p_c , the greater will be the length $L(x)$ of a typical path between two nodes, which are geometrically a distance x apart.

Expressing the *Kozeny-Carman (KC)* equation in terms of the hydraulic radius as

$k = \frac{R_{HYD}^2}{b} \cdot \Phi \cdot \frac{1}{\tau^2}$, (more precisely, $k[md] = \frac{(R_{HYD}[mm])^2}{b} \cdot \Phi \cdot \frac{1}{\tau^2} \cdot 10^9$), let λ denote the volume fraction of kaolinite, Φ porosity, then the ratio of open pore space to the total space filled by pores or clays is $p = \frac{\Phi}{\Phi + (1 - \Phi)\lambda}$. The tortuosity tends to infinity with $p \rightarrow p_c$, $p > p_c$ as $\tau \propto (p - p_c)^{-\nu}$, that is $\frac{1}{\tau^2} \propto (p - p_c)^{\nu^2}$. Define a percolation function PERC as

$$PERC = \begin{cases} 0 & \text{if } p \leq p_c \\ C_0(p - p_c)^{\nu^2} = C_0(p - p_c)^{PERC} & \text{if } p > p_c \end{cases}$$

where $PERC = \nu^2$, the normalizing constant C_0 is chosen such as to make $PERC(1) = 1$, that is $C_0 = 1/(1 - p_c)^{PERC}$. To find the prefactor in the asymptotic law $\frac{1}{\tau^2} \propto (p - p_c)^{\nu^2}$, we consider clean sand with $\lambda = 0$ kaolinite content, in which case $p = 1$ and $PERC(1) = 1$, that is for τ_0 we can choose a reasonable average tortuosity for clean sands, say $\tau_0 = 4$. Geometrical considerations give $R_{HYD} = \frac{1}{3} \cdot \frac{\Phi + (1 - \Phi)\lambda}{(1 - \Phi)(1 - \lambda)} \cdot r \sqrt{p}$ (where Φ , $\lambda \neq 1$, r is mean grain radius). The final expression for k becomes, as function of Φ , r , Z , λ (porosity, grain radius, coordination number, and kaolinite volume content):

$$k = \begin{cases} \frac{R_{HYD}^2}{b\tau_0^2} \cdot \Phi \cdot 10^9 \cdot \left(\frac{p - p_c}{1 - p_c}\right)^{PERC} & p \geq p_c \\ 0 & p < p_c \end{cases} \quad (54)$$

with $b = 2$, $\tau_0 = 4$, $p_c = 1.5/Z$; $p = \frac{\Phi}{\Phi + (1 - \Phi)\lambda}$; $R_{HYD} = \frac{1}{3} \cdot \frac{\Phi + (1 - \Phi)\lambda}{(1 - \Phi)(1 - \lambda)} \cdot r \sqrt{p}$.

Renormalization Group (RNG) Models of Rock Failure

How can we find the *critical* percolation probability p_c , or the *critical number* of cracks per unit volume that make an originally solid rock fall to pieces? Such questions of rock physics can be solved by the *Renormalizations Group* method of Statistical Physics (where it had been adopted from *Quantum Field Theory*). In the *RNG* approach, to study the critical behavior of a large system, we first consider its smaller subsystems, find their behavior, and then we put them together and express in terms of them the behavior of a larger-scale subsystem. Suppose that each of the n th order subsystems can be in one of the states $S_1, S_2, \dots, S_K$ with probabilities $p_1^{(n)}, p_2^{(n)}, \dots, p_K^{(n)}$ ($\sum_{i=1}^K p_i^{(n)} = 1$). Similarly, any $(n+1)$ st-order subsystem belongs to state S_i with probability $p_i^{(n+1)}$, ($\sum_{i=1}^K p_i^{(n+1)} = 1$). The distributions $\{p_i^{(n+1)}\}$ and $\{p_i^{(n)}\}$ are related by a system of K nonlinear equations

$$\begin{array}{rcl} p_1^{(n+1)} & = & F_1 \left[p_1^{(n)}, p_2^{(n)}, \dots, p_K^{(n)} \right] \\ \dots & \dots & \dots \\ p_K^{(n+1)} & = & F_K \left[p_1^{(n)}, p_2^{(n)}, \dots, p_K^{(n)} \right] \end{array} \quad (55)$$

where the functions F_i depend on the physical properties of the states, and on the geometry as the $(n + 1)$ st-order subsystems are put together from the n th order ones (“*coarse-graining*”). The *critical probabilities* are solutions of Eq. (55) in the limit $n \rightarrow \infty$:

$$\begin{aligned} p_1^{(\text{crit})} &= F_1 \left[p_1^{(\text{crit})}, p_2^{(\text{crit})}, \dots, p_K^{(\text{crit})} \right] \\ &\vdots \quad \quad \quad \vdots \\ p_K^{(\text{crit})} &= F_K \left[p_1^{(\text{crit})}, p_2^{(\text{crit})}, \dots, p_K^{(\text{crit})} \right] \end{aligned} \quad (56)$$

In the case of *rock damage* (Allègre et al. 1982) there are only two states (fragile/sound) with probabilities $p^{(n)}, q^{(n)}$; $p^{(n)} + q^{(n)} = 1$ in the n th step of coarse-graining, that is Eqs. (55 and 56) become $p^{(n+1)} = F[p^{(n)}]$ and, for $n \rightarrow \infty$, $p_c = F(p_c)$.

Coarse-graining is based on the observation, that rock failure is consequence of fractures, a fracture is consequence of microfissures, and a microfissure is consequence of microcracks. This is shown in Fig. 1 where each block in the n th step can be *fragile* or *sound* with probabilities $p^{(n)}$ and $1 - p^{(n)}$.

Define a cubic cell “fragile” if it contains no continuous pillar connecting any two opposite faces. Otherwise, the cell is “sound.” Summing up the probabilities of all possible fragile configurations (with multiplicities because of topological equivalence) and letting $n \rightarrow \infty$ the critical probability satisfies the algebraic equation $p = p^4(3p^4 - 8p^3 + 4p^2 + 2)$, whose nontrivial solution is $p_c = 0.896$. We note that a

Statistical Rock Physics, Fig. 1 Coarse graining. (From Allègre et al. 1982)

different definition (Turcotte 1986) of “fragility” would lead to another equation $p = 3p^8 - 32p^7 + 88p^6 - 96p^5 + 86p^4$ whose acceptable solution yields quite a different (and more realistically!) $p_c = 0.49$.

Discrete Scale Invariance

In May, 2006, a mud volcano erupted in Java, triggered by the drilling of an oil exploration well. The pressure created by the drilling was sufficient to break an about 1800 m long connected path for the deep mud to propagate up to the surface. Can we understand, simulate, and predict such overall failures of solid rock massifs using *Renormalization Group (RNG)* and *Phase Transition Theory*?

Suppose there exists a function $F(t)$ of time (or of temperature, pressure, porosity, etc.) that can be continuously measured and which behaves as an *order parameter* in the sense of *Landau's theory of second order phase transitions*, that is, it is identically zero on one side of the phase transition, while nonzero and increasing as a power function on the other side, changing its behavior at a critical time instant t_c . How can one find such an $F(t)$ and the critical time-instant t_c ?

A way to solve this is to assume *Discrete Scale Invariance* (Saleur et al. 1996; Sornette 1998) at the critical time t_c . Suppose a system undergoes phase transition (nonconductive $\rightarrow$ conductive, predictable $\rightarrow$ chaotic, solid $\rightarrow$ damaged, etc.). In

Statistical Rock Physics, Table 3 Lopatin's TT index and corresponding stages of CH generation. (From Waples 1980)

TTI	Stage
15	Onset of oil generation
75	Peak oil generation
160	End of oil generation
~500	40° oil preservation deadline
~1000	50° oil preservation deadline
~1500	Wet gas preservation deadline
>65,000	Dry gas preservation deadline

case of *scale invariance*, the order parameter $F(t)$ satisfies $F(0) = 0$ and $F(\lambda|t - t_c|) = \mu(\lambda) F(|t - t_c|)$ for all $\lambda > 0$. This is Pexider's functional equation (Korvin 1992b: 75–76), whose solution is $\mu(\lambda) = \lambda^\alpha$; $F(|t - t_c|) = |t - t_c|^\alpha$, that is F behaves as a *power function*. In case of *discrete scale invariance* $F(\lambda|t - t_c|) = \mu(\lambda) F(|t - t_c|)$ only holds for a *finite set* of the λ values, $\lambda = \lambda_1, \lambda_2, \dots, \lambda_n$. For the case $\lambda_k = \lambda^k$ and letting $\tau = |t - t_c|$ we have

$$F(\tau) = \tau^\alpha \cdot \Theta\left(\frac{\log \tau}{\log \lambda}\right)$$

where Θ is a periodic function. Fourier expanding to first order:

$F(\tau) = A + B\tau^\alpha + C\tau^\alpha \cos(\omega \cdot \log \tau - \varphi)$ with $\omega = 2\pi/\log \lambda$, that is at phase transition the power-function-like increase is “decorated” with *logperiodic corrections*. The unknown parameters of the Fourier expansion, $A, B, C, t_c, \alpha, \lambda, \varphi$ can be found with nonlinear fitting. (An approximate value of t_c might be found from *RNG*.)

Arrhenius Law and Source-Rock Maturity

In Physical Chemistry, according to the *Arrhenius equation*, the rate r of chemical processes exponentially grows with temperature: $r = A \cdot \exp[-E_a/RT]$ where A is a constant, E_a activation energy, R the universal gas constant, and T absolute temperature. In *Basin Analysis* (Waples 1980; Lerche 1990), Arrhenius equation is our main tool to estimate the *maturation of hydrocarbon* in source rocks, in the knowledge of the basin's burial-temperature-time history. The summary effect of increasing temperature $T(t)$ during a geological time window $[t_1, t_2]$ is given by the *maturation integral* $A \cdot \int_{t_1}^{t_2} \exp[-E_a/RT(t)] dt + C_0$. For hydrocarbon maturation, the constant E_a/R is selected such as to satisfy the empirical finding that in the 50°C – 250°C temperature range, and for typical reservoir pressures, the rate of decomposition of organic materials doubles at every 10°C temperature rise. If one selects $A = 1$, $C_0 = 0$, and the integral is substituted by a discrete sum, it will go over to Lopatin's *Time Temperature Index (TTI)* = $\sum_k \Delta t_k \cdot 2^k$ where Δt_k is the time (in million years)

spent in the heat-window $100^\circ\text{C} + 10 \cdot k^\circ\text{C} \leq T_0 \leq 100^\circ\text{C} + 10 \cdot (k+1)^\circ\text{C}$; $k = 0, \pm 1, \pm 2, \dots$. N.V. Lopatin used TTI in the 1970s to predict the thermal maturation of coal. Both for coal and HC good correlation has been established between TTI and vitrinite reflection, which is a microscopically determinable measure of maturity. The threshold values given in Table 3 connect Lopatin's TT index to the distinct stages of CH generation.

Conclusions

Apart from living organisms, rocks are the most complex objects in the world. Prediction of their *effective* physical properties (such as elastic moduli, hydraulic or electric conductivity) based on their mineralogical composition and internal geometry as function of geologic age, depth, pressure, and temperature is the basic task of Geophysics, Geodynamics, and Geomechanics. Because of the inherent randomness of rocks, this task requires the powerful tools developed for treating random systems of an abundant number of degrees of freedom. This chapter described some recent Rock Physical applications of *Stochastic Geometry* and *Statistical Physics*. To help readers to follow recent developments, and to apply these techniques in their own research, each technique was described in a self-contained manner, and illustrated by actual examples. We foresee that similar to the Edwards-style *Statistical Physics of Granular Materials* (Makse et al. 2004) *Statistical Rock Physics* would become an important, independent part of *Condensed Matter Physics*.

Statistical Seismology

Jiancang Zhuang

The Institute of Statistical Mathematics, Research
Organization of Information and Systems, Tokyo, Japan

Synonyms

Earthquake statistics; Seismometrics; Seismostatistics

Definition

The terminology statistical seismology can be considered from two different perspectives or scopes: special and general. The special scope is similar to that used in statistical physics. Statistical seismology aims to develop stochastic models that describe the patterns of seismicity, along with related statistical inferences, to understand the physical mechanisms of earthquake occurrence and produce probability forecasts of earthquakes. The general scope of statistical seismology includes the use of statistical methods related to traditional seismology, such as Bayesian methods in geophysical inversion. Synonyms of statistical seismology include “seismometrics” and “seismostatistics.” Generally, statistical seismology falls under the special scope. Knowledge of this interdisciplinary subject has been widely applied in earthquake physics, earthquake forecasting, and earthquake engineering. This chapter only considers topics under the special scope.

Historical Overview

The term “statistical seismology” first appeared in a paper, titled “An Application of the Theory of Fluctuation to Problems in Statistical Seismology,” by Kishinouye and Kawasumi (1928) in the *Bulletin of the Earthquake Research Institute, Tokyo Imperial University*, 4, 75–83 (Fig. 1). This term was then used by Keiti Aki in a paper, titled “Some problems in statistical seismology” in Japanese on *Zisin* in 1956. In 1995, David Vere-Jones gave lectures on the statistical analysis of seismicity at the Graduate School of Chinese Academy of Science (now the University of Chinese Academy of Science) in Beijing. As suggested by Yaolin Shi, he named the lecture “statistical seismology” (Vere-Jones 2001). At present, this subject has become an important branch of seismology, serving as a bridge between seismic-waveform dominant traditional seismology and tectonics/geodynamics by providing theoretical and technical tools for analyzing seismicity.

The history of statistical seismology can be roughly divided into three episodes:

- Episode I: Exploration and accumulation of simple individual empirical laws
- Episode II: Construction of a theoretical framework and development of time-dependent forecasting models
- Episode III: Model development and forecasting and testing attempts

This chapter presents an episode-wise discussion of the concepts, theories, and methods in statistical seismology according to the above timeline.

Episode I: Exploration and Accumulation of Simple Individual Empirical Laws

This period started at the beginning of the twentieth century. In 1982, John Milne, James Ewing, and Thomas Cray installed the first model seismometer in Japan, marking the start of modern *seismology*. Seismometers enable the detection of the occurrence of global earthquakes, such that we can calculate their occurrence time and hypocenter locations and compile relatively complete earthquake catalogs. The primary applications of statistics in earthquake studies during this period were simple statistical techniques, such as linear regression and point estimates, among others, scattered among individual studies on different topics. The following subsections summarize the main findings during this stage.

The Gutenberg-Richter Law for the Magnitude-Frequency Relationship

In 1944, Gutenberg and Richter published a formula describing the relationship between any magnitude, e.g., m , and the number of earthquakes in any given region and period (Gutenberg and Richter 1944):

$$\log_{10} N(\geq m) = a - bm, \quad \text{or,} \quad N = 10^{a-bm}, \quad (1)$$

where $N(\geq m)$ is the number of earthquakes with a magnitude no less than m in the given region and period and b is the so-called Gutenberg-Richter b -value. In probability terms:

$$\begin{aligned} \Pr\{\text{magnitude} \geq m \mid \text{magnitude} \geq m_c\} &\approx \frac{N(\geq m)}{N(\geq m_c)} \\ &= \frac{10^{a-bm}}{10^{a-bm_c}} = 10^{-b(m-m_c)}. \end{aligned} \quad (2)$$

Therefore, the cumulative distribution function (c.d. f. or cdf) for the magnitude distribution is as follows:

An Application of the Theory of Fluctuation to Problems in Statistical Seismology.

by

Fuyuhiko KISHINOUE and Hiroshi KAWASUMI.

The object of this investigation is to introduce the application of the theory of fluctuation to some problems of statistical seismology. We have investigated the fluctuation of the number of earthquakes instrumentally registered in some units of time, taking the statistical after-effect into consideration.

The theory here applied is that given in R. Fürth: Schwankungserscheinungen in der Physik (1920, Sammlung Vieweg, Heft 48), especially in the chapter dealing with "die Schwankungen mit Wahrscheinlichkeitsnachwirkung bei intermittierende Beobachtung." A brief sketch of the theory concerned in our investigation is as follows.

Suppose that a trial consists of a great number, N , of events, and the probability of a favourable event is a very small number p , while the number of favourable events in a trial, $n = Np$, is finite. Then the probability of obtaining n favourable events in a trial, $W(n)$, is given by Poisson's formula,

$$W(n) = \frac{e^{-\nu} \nu^n}{n!}, \text{ where } \nu \text{ is the mean value of } n.$$

If we take a great number of trials in succession and the interval of each trial be constant (τ), the velocity of fluctuation $\mathcal{A} = n_1 - n_2$, the mean duration T , and the time of recurrence Θ of n favourable events, can be calculated theoretically, if we know the law which governs the appearance of n_2 favourable events after n_1 favourable events. This after-effect of n_1 on n_2 is here assumed to be effective on the next trial only, and the probability that a favourable event in a trial turns out unfavourable in the next is also assumed to be a constant P .

Then the probability that $n \pm k$ favourable events occur after n favourable events, $W(n, n \pm k)$, as well as $\bar{\mathcal{A}}(n)$, $\bar{\mathcal{A}}^2$, $T(n)$, $\Theta(n)$, and the probability of lasting

$$\begin{aligned}
F(m) &= \Pr\{\text{magnitude} \leq m\} \\
&= 1 - \Pr\{\text{magnitude} \geq m\} \\
&= \begin{cases} 1 - 10^{-b(m-m_c)}, & \text{if } m \geq m_c, \\ 0, & \text{otherwise,} \end{cases} \quad (3)
\end{aligned}$$

and the corresponding probability density function (p.d.f. or pdf) is as follows:

$$\begin{aligned}
f(m) &= \begin{cases} b 10^{-b(m-m_c)} \ln 10, & \text{if } m \geq m_c; \\ 0, & \text{otherwise,} \end{cases} \\
&= \begin{cases} \beta e^{-\beta(m-m_c)} & \text{if } m \geq m_c; \\ 0, & \text{otherwise,} \end{cases} \quad (4)
\end{aligned}$$

where β is linked with b by $\beta = b \ln 10 \approx 2.3026b$.

The Omori-Utsu Formula for the Aftershock Frequency

The Omori-Utsu formula describes the decay of the aftershock frequency with time after the mainshock, as an inverse power law. Omori (1894) examined the aftershocks of the 1891 $M_s 8.0$ Nobi earthquake, first attempting to use an exponential decay function to fit the data, but unsatisfactory results were obtained. Afterward, it was found that the number of aftershocks occurring each day can be described by the equation:

$$n(t) = K(t + c)^{-1}, \quad (5)$$

where t is the time from the occurrence of the mainshock, and K and c are constants.

Utsu (1957) postulated that the decay of the aftershock numbers can vary, proposing the following equation:

$$n(t) = K(t + c)^{-p}, \quad (6)$$

which yields better fitting results. Equation (6) is referred to as the modified Omori formula or the Omori-Utsu formula.

The Omori-Utsu formula has been used extensively to analyze, model, and forecast aftershock activity. Utsu et al. (1995) reviewed the values of p for more than 200 aftershock sequences, finding that this parameter ranges from 0.6 to 2.5, with a median of 1.1. No clear relationship between the estimates of the p -values, and the mainshock magnitudes was found.

Not only do mainshocks trigger aftershocks, but large aftershocks can also trigger their own aftershocks. To model such phenomena, Utsu (1970) used the following *multiple Omori-Utsu formula*:

$$\lambda(t) = K/(t - t_0 + c)^{-p} + \sum_{i=1}^{N_T} \frac{K_i H(t - t_i)}{(t - t_i + c_i)^{-p_i}}, \quad (7)$$

where t_0 is the occurrence time of the mainshock, t_i , $i = 1, \dots, N_T$ define the occurrence times of the triggering aftershocks, and H is the Heaviside function. The likelihood for the multiple Omori-Utsu formula is slightly more complicated than that for the simple Omori-Utsu formula but can be written in a similar manner.

One difficulty in applying the multiple Omori-Utsu formula is to determine which earthquakes have triggered an event. The largest aftershocks often (but not always) have secondary aftershocks. We can use the techniques of residual analysis described in the section as a diagnostic tool, to understand which events have secondary aftershocks.

The Båth Law for the Maximum Magnitude of Aftershocks and Other Scaling Laws

Another well-known empirical law in earthquake clusters is the Båth law, which asserts that the magnitude difference between the mainshock and the largest aftershock has a median of 1.2 (Båth 1965). A more general form proposed by Utsu (1961) has the following form:

$$M_0 - M_1 = c_1 M_0 + c_2, \quad (8)$$

where c_1 and c_2 are constants and M_0 and M_1 are the magnitudes of the mainshock and its largest aftershock, respectively. This law is useful for evaluating the possible loss caused by aftershocks.

Many empirical scaling laws related to earthquake magnitude were established during this period, including the following:

1. Several empirical laws for the relationship between the Richter magnitude, M_L Richter 1935, and the amplitude, A , of waves recorded at seismographs. For example, the Lilie empirical formula is as follows:

$$M_L = \log_{10} A - c_1 + c_2 \log_{10} \Delta, \quad (9)$$

where Δ is the epicenter distance and c_1 and c_2 are constants.

2. Relationship among the shaking intensity, I_0 , at the epicenter, magnitude, M , and focal depth, h (e.g., Gutenberg and Richter 1942):

$$M = a_0 I_0 + a_1 \log h - a_2, \quad (10)$$

where a_0 , a_1 , and a_2 are constants.

3. Scaling relationship between the number, N , of aftershocks and the size, M , of the mainshock (Yamanaka and Shimazaki 1990):

$$\log_{10} N = c \log_{10} M - d, \quad (11)$$

where c and d are constants.

4. Seismic moment, M_0 , scaling with the fault area, S (Kanamori and Anderson 1975):

$$\log_{10} S = a_0 \log_{10} M_0 - a_1, \quad (12)$$

or fault length, L (Shimazaki 2013):

$$\log_{10} L = b_0 \log_{10} M_0 - b_1, \quad (13)$$

where a_0 , a_1 , b_0 , and b_1 are constants.

Most empirical studies have been based on simple linear regressions.

Episode II: Construction of a Theoretical Framework and Development of Time-Dependent Forecasting Models

This stage began in the 1970s with two milestones: the introduction of the point process model and the development of the theory of conditional intensity in the point process. First, the development of stochastic models for earthquake risks was a requirement for earthquake engineering. Building codes, with respect to the design of a building structure, required the consideration of the probability of the occurrence of the largest ground-shaking event for a specific period into the future. In earthquake engineering, the stationary Poisson model (also referred to as the time-independent model) was often used to estimate the future earthquake hazard.

Considered as a classic reference, Vere-Jones (1970) proposed the point process to describe the process of earthquake occurrence times, focusing on the tools required to generate a functional and spectrum analysis. Vere-Jones (1973) introduced the use of the conditional intensity in statistical seismology, which is defined as the expectation of earthquake occurrence under the condition of previous knowledge on the earthquake process and/or external observations.

The core idea of model development is bringing into existing stochastic models with more nonrandomness based on physical theory and observations. During this episode, for long-term earthquake hazard evaluations, renewal models were developed by modifying the inter-event time in the Poisson model to more general random distributions. The stress release model was developed by adding Reid's elastic rebound theory to the rate function of the Poisson model. For short-term earthquake forecasting, the Reasenberg and Jones

model and the ETAS model were developed based on the Omori-Utsu formula.

Basic Formulation

Point process modeling is the key tool in statistical seismology for describing the occurrence of earthquakes, where some probabilistic rules are specified for the occurrence of earthquakes in time and/or space. When some other quantities, such as intensities or magnitudes, are attached to each event, the point process is then referred to as a marked point process.

Introduction to Conditional Intensity

Denote a point process, in time by N , and a certain temporal location, by t . We assume in the following discussion that we have known observations up to time t . The most important characteristic is the waiting time u to the next event from time t . We can therefore consider the following cumulative probability distribution function of the waiting time:

$$F_t(u) = \Pr\{\text{from } t \text{ onward, waiting time to next event} \leq u \mid \text{observations before } t\}, \quad (14)$$

with the corresponding probability density function:

$$f_t(u)du = \Pr\{\text{from } t \text{ onward, waiting time is between } u \text{ and } u + du \mid \text{observations before } t\}, \quad (15)$$

The survival function can be defined as follows:

$$S_t(u) = \Pr\{\text{from } t \text{ onward, waiting time} > u \mid \text{observations before } t\} \\ = \Pr\{\text{No event occurs between } t \text{ and } t + u \mid \text{observations before } t\}. \quad (16)$$

The hazard function can be defined as follows:

$$h_t(u)du = \Pr\left\{\begin{array}{l} \text{next event occurs between} \\ t+u \text{ and } t+u+du \end{array} \middle| \begin{array}{l} \text{Observations before } t \text{ and that no} \\ \text{event occurs between } t \text{ and } t+u \end{array}\right\} \quad (17)$$

Finally, the cumulative hazard function can be defined as

$$\Lambda_t(u) = \int_0^u h_t(s) ds. \quad (18)$$

These functions are related in the following manner:

$$S_t(u) = 1 - F_t(u) = \int_u^\infty f_t(s) ds = \exp\left[-\int_0^u h_t(s) ds\right] \\ = \exp[-\Lambda_t(u)], \quad (19)$$

$$\begin{aligned} f_t(u) &= \frac{dF_t}{du} = -\frac{dS_t}{du} = h_t(u) \exp \left[-\int_0^u h_t(s) ds \right] \\ &= \exp[-\Lambda_t(u)] \frac{d\Lambda_t(u)}{du}, \end{aligned} \quad (20)$$

$$\begin{aligned} h_t(u) &= \frac{f_t(u)}{S_t(u)} = -\frac{d}{du} [\log S_t(u)] \\ &= -\frac{d}{du} [\log(1 - F_t(u))] = \frac{d\Lambda_t(u)}{du}, \end{aligned} \quad (21)$$

$$\begin{aligned} \Lambda_t(u) &= -\log S_t(u) = -\log[1 - F_t(u)] \\ &= -\log \left[1 - \int_0^u f_t(s) ds \right]. \end{aligned} \quad (22)$$

Using the above formulas, if a random variable, W , represents the waiting time, which has a cumulative distribution function of $F_t(\cdot)$, then $F_t(W)$ belongs to a uniform distribution on $[0, 1]$; consequently, $\Lambda_t(W)$ follows an exponential distribution of the unit rate.

In the above concepts, the hazard function h_t has the property of additivity; the hazard function of the superposition of two subprocesses is the sum of the two hazard functions of these subprocesses. Additionally, if there is no event occurring between t and $t + u$, and $v \geq u \geq 0$, then $h_t(v) = h_{t+u}(v - u)$. Thus, $h_t(0)$ is identical to $h_{t'}(t - t')$ for any time t' between t and the occurrence time of the previous event. Assuming left-continuity with t , the function $h_t(0)$ is referred to specifically as the conditional intensity, denoted by $\lambda(t)$ or $\lambda(t | \mathcal{H}_t)$, where $\mathcal{H}_t$ represents the observation history up to time t , but does not include t . Based on the definition of the hazard function, we can obtain the following:

$$\lambda(t)dt = \Pr\{\text{one or more events occur in } [t, t + dt) | \mathcal{H}_t\}. \quad (23)$$

This is typically used as the definition of *conditional intensity*. When the point process, N , is simple, i.e., there is at most one event occurring at the same time and location, then $\Pr\{N[t, t + dt) > 1\} = o(dt)$. Using this relationship, $\lambda(t)$ can also be defined as follows:

$$\mathbf{E}[N[t, t + dt) | \mathcal{H}_t] = \lambda(t)dt + o(dt). \quad (24)$$

This process becomes a stationary Poisson process when $h_t(u)$ is a constant.

Likelihood, Maximum Likelihood Estimate, and AIC

Given an observed dataset of a point process, N , say $\{t_1, t_2, \dots, t_n\}$, in a given time interval $[S, T]$, the likelihood function, L , is the joint probability density of the waiting times for each of these events, which can be written as

$$L(N; S, T) = \left[\prod_{i=1}^n \lambda(t_i) \right] \exp \left[-\int_S^T \lambda(u) du \right], \quad (25)$$

or in logarithm form:

$$\log L(N; S, T) = \sum_{i=1}^n \log \lambda(t_i) - \int_S^T \lambda(u) du. \quad (26)$$

A direct use of the likelihood function is parameter estimation: When the model involves some unknown regular parameters, e.g., θ , we can estimate θ by maximizing the likelihood, i.e., the MLE (maximum likelihood estimate) is

$$\hat{\theta} = \arg_{\theta} \max L(N; S, T; \theta). \quad (27)$$

If several models fit to the same dataset, the optimal model can be selected using the Akaike information criterion (AIC, see Akaike 1974). The statistic

$$AIC = -2 \max_{\theta} \log L(\theta) + 2k_p \quad (28)$$

is computed for each model fit to the data, where k_p is the total number of estimated parameters for a given model. Based on a comparison of models with different numbers of parameters, the addition of $2k_p$ roughly compensates for the additional flexibility provided by the extra parameters. The model with the lowest AIC value is the optimal choice for forward prediction purposes.

Transformed Time Sequence and Residual Analysis

Residual analysis is a powerful and widely used tool for assessing the fit of a particular model to a set of occurrence times (e.g., Ogata 1988). Assume that we have a realization of a point process with event times denoted by $t_1, t_2, \dots, t_n$. We can then calculate the transformed event times, denoted by $\tau_1, \tau_2, \dots, \tau_n$, in such a manner that they have the same distributional properties as the homogeneous Poisson process with a unit rate parameter. If we suppose that the conditional intensity is $\lambda(t)$, the transformed time sequence for $i = 1, 2, \dots, n$, is calculated with

$$\tau_i = \int_0^{t_i} \lambda(u) du. \quad (29)$$

The sequence $\{\tau_i : i = 1, 2, \dots, n\}$ then forms a Poisson process with a unit rate as the above transformation modifies the waiting time into an exponential random variable with a unit rate.

This method can be used to test the goodness-of-fit of the model. If the fitted model, $\hat{\lambda}(t)$, is close enough to the true model, then $\{\hat{\tau}_i = \int_0^{t_i} \hat{\lambda}(u) du : i = 1, 2, \dots, n\}$ is similar to the

standard Poisson model. The deviation of the rate in the transformed time sequence from the unit rate indicates either increased activity or quiescence relative to the seismic rate based on the original model.

Models Developed in Episode II

Renewal/Recurrence Models

A renewal process is a generalization of the Poisson process. The Poisson process has independent identically distributed waiting times that are exponentially distributed before the occurrence of the next event; however, a renewal process has a more general distribution for the waiting times. This indicates that the time interval between any two adjacent events is independent from the other intervals; the occurrence of the next event depends only on the time of the last event, but not on the full history.

Renewal models yield the characteristic recurrence of earthquakes along a fault or in a region. This class of models is widely used in seismicity and seismic hazard analysis. For example, Field (2007) summarized how the Working Group on California Earthquake Probabilities (WGCEP) estimates the recurrence probabilities of large earthquakes on major fault segments using various recurrence models to produce the official California seismic hazard map. These models sometimes use the elastic rebound theory proposed by Reid (1910). According to this theory, large earthquakes release elastic strain that has accumulated since the last large earthquake. Some seismologists have deduced that longer quiescence periods indicate a higher probability of an imminent event (e.g., Nishenko and Buland 1987), whereas others contend that the data contradict this view (e.g., Kagan and Jackson 1995). Renewal models are often used to quantitatively demonstrate whether earthquakes occur temporally in clusters or quasiperiodically.

If we denote the density function of the waiting times by $f(\cdot)$, which is also usually referred to as the renewal density, the conditional intensity of the renewal process is the same as the hazard function:

$$\lambda(t) = \frac{f(t - t_{N(t_-)})}{1 - F(t - t_{N(t_-)})}, \quad (30)$$

where $t_{N(t_-)}$ is the occurrence time of the last event before t and F is the cumulative probability function of f .

The following probability functions are often selected as the renewal densities:

- The **gamma renewal** model has a density defined as follows:

$$f(u; k, \theta) = u^{k-1} \frac{e^{-u/\theta}}{\theta^k \Gamma(k)}, \quad \text{for } u \geq 0 \text{ and } k, \theta > 0, \quad (31)$$

where θ is the scale parameter, k is the shape parameter, and Γ and Γ_α are the gamma and incomplete gamma functions, respectively, defined by $\Gamma(x) = \int_0^\infty t^{x-1} e^{-t} dt$ and $\Gamma_\alpha(x) = \int_x^\infty t^{x-1} e^{-t} dt$.

- The **log-normal renewal** model has a density function defined as follows:

$$f(u; \mu, \sigma) = \frac{1}{u\sigma\sqrt{2\pi}} e^{-\frac{(\ln(u)-\mu)^2}{2\sigma^2}}, \quad \text{for } u \geq 0, \quad (32)$$

where μ and σ are the mean and standard deviation of the variable's natural logarithm, respectively, and erf is the error function.

- The Weibull distribution, used in the **Weibull renewal** model, is one of the most widely used lifetime distributions in reliability engineering. The probability density function of a Weibull random variable, X , is defined as follows:

$$f(u; \mu, k) = \begin{cases} \frac{k}{\mu} \left(\frac{u}{\mu}\right)^{k-1} e^{-(u/\mu)^k} & u \geq 0, \\ 0 & u < 0, \end{cases} \quad (33)$$

where $k > 0$ is the shape parameter and $\mu > 0$ is the scale parameter of the distribution.

- Brownian passage time model Kagan and Knopoff (1987) used an inverse Gaussian distribution to model the evolution of stress as a random walk with tectonic drift. Matthews et al. (2002) then proposed the *Brownian passage-time model* based on the properties of the Brownian relaxation oscillator (BRO). In this conceptual model, the loading of the system has two components: (1) a constant-rate loading component, λt , and (2) a random component, $\varepsilon(t) = \sigma W(t)$, defined as a Brownian motion (where W is a standard Brownian motion and σ is a nonnegative scale parameter. The Brownian perturbation process for the state variable, $X(t)$, (see Matthews et al. 2002) is defined as:

$$X(t) = \lambda t + \sigma W(t).$$

An event will occur when $X(t) \geq X_c$. These event times can be observed as the “first Passage” or “hitting” times of Brownian motion with drift. The BRO is a family of stochastic renewal processes defined by four parameters: the drift or

mean loading (λ), perturbation rate (σ^2), ground state (X_0), and failure state (X_f). In fact, the recurrence properties of the BRO (response times) can be described by a Brownian passage-time distribution, which is characterized by two parameters: (1) the mean time or period between events, (μ), and (2) the aperiodicity of the mean-time, α , which is equivalent to the coefficient of variation (defined as the ratio of the variance to the mean occurrence time). The probability density for the Brownian passage-time (BPT) model is given by

$$f(t; \mu, \alpha) = \left(\frac{\mu}{2\pi\alpha^2 t^3} \right)^{\frac{1}{2}} \exp \left\{ -\frac{(t - \mu)^2}{2\alpha^2 \mu t} \right\}, \quad t \geq 0 \quad (34)$$

with a cumulative probability function

$$F(t; \mu, \alpha) = \Phi \left(\frac{t - \mu}{\alpha \sqrt{\mu x}} \right) + \exp \left(\frac{2}{\alpha^2} \right) \Phi \left(-\frac{t + \mu}{\alpha \sqrt{\mu x}} \right), \quad (35)$$

where Φ is the cumulative probability distribution function of a standard normal random variable, i.e., F , which is the inverse Gaussian or Wald distribution.

Among the models described above, the BPT model has become the most popular, which has been used to obtain interesting results. However, there is no clear evidence showing that one model is superior to the others. This may be caused by the relatively large standard errors for the parameter estimates owing to scarce data points in the historical catalogs. Another is that this may also be due to the nature of renewal processes (e.g., Daley and Vere-Jones 2003, pages 77–79): The superposition of independent nontrivial renewal processes does not result in a renewal process unless all of the superposed processes are simply Poisson processes. This property requires that the renewal process be applied to a fault system that is relatively disjoint in behavior from the surrounding environment or is loaded by a constant tectonic stress rate. However, the identification of such fault systems appears to be technically difficult in practice.

Stress Release Model

The stress release model was proposed in a series of studies by Vere-Jones and others (see, for example, Zheng and Vere-Jones 1991) by introducing randomness into the elastic rebound theory (Reid 1910). This model assumes that the stress level in a specific region gradually builds in a linear manner with time as a result of tectonic movements, dropping suddenly with the occurrence of an earthquake, i.e., the stress level at t , $X(t)$, can be written as follows:

$$X(t) = X(0) + \rho t - S(t), \quad (36)$$

where $X(0)$ is the initial stress level, ρ is the constant loading rate from the tectonic movement, and $S(t)$ is the accumulated

stress release from earthquakes during period $[0, t)$, such that we have the following:

$$S(t) = \sum_{i: t_i < t} s_i. \quad (37)$$

Stress release related to individual earthquakes is assumed to be independent of the stress level and to scale with the magnitude m_i :

$$s_i = 10^{0.75 m_i} \quad (38)$$

as indicated by the Benioff strain. The conditional intensity is a monotonically increasing function of the stress level, usually selected as:

$$\begin{aligned} \lambda(t) &= \Psi(X) = e^{\gamma X} = \exp[\gamma(X(0) + \rho t - S(t))] \\ &= \exp[a + bt - cS(t)], \end{aligned} \quad (39)$$

where γ is a single parameter representing the strength and heterogeneity of the regional crust and $a = \gamma X(0)$, $b = \rho\gamma$, and $c = \gamma$ are the final model parameters. The assumption of an exponential distribution agrees with laboratory experiments on stress corrosion, where the mean waiting time until fracture can be approximated by an exponential function of the negative applied stress.

Reasenbergs-Jones Model

During the 1980s and 1990s, Reasenbergs and Jones (1989) combined the Gentengburg-Richter magnitude-frequency relationship and Omori-Utsu formula to forecast aftershock activities.

The conditional intensity for the full model can be expressed as:

$$\lambda(t, m) = \frac{Ks(m)}{(t + c)^p}, \quad (40)$$

where $s(m)$ is the magnitude probability density function, usually taking the form of the Gutenberg-Richter magnitude-frequency relation.

Self- and Mutually Exciting Models

Hawkes' mutual excitation model, also referred to as the self-exciting and mutually exciting earthquake models, was developed by Utsu and Ogata (see Utsu and Ogata 1997) based on the Hawkes process (Hawkes (1971)). The conditional intensity function can be written as follows:

$$\lambda(t) = \mu(t) + \sum_{i: t_i < t} g(t - t_i) + \sum_{j: s_j < t} g(t - s_j) \quad (41)$$

where $\mu(t)$ represents the background rate, which may be a function of time, but it is deterministic, i.e., it does not depend on the observation history, and $g(t)$ and $h(t)$ represent the self-exciting and external excitation terms of earthquakes inside and outside of the region, respectively. The excitation terms, $g(t)$ and $h(t)$, are in the form of a sum of the Laguerre polynomials:

$$g(t) = e^{-\alpha t} \sum_{k=0}^{K_1} p_k t^k, \quad h(t) = e^{-\beta t} \sum_{k=0}^{K_2} q_k t^k, \quad (42)$$

where K_1 and K_2 are nonnegative integers and $p_1, p_2, \dots, p_{K_1}$, $\alpha, q_1, q_2, \dots, q_{K_2}$, β are model parameters for estimation. The determination of the number of parameters, K_1 and K_2 , in the Laguerre expansions can be performed using the AIC. This model was used in earlier studies primarily to investigate possible triggering effects between different types of seismicity or the existence of precursory information in observations from non-seismic geophysical variables.

ETAS Model

In most cases, the aftershock activity consists of a secondary aftershock clustering, as described by the multiple Omori-Utsu formula (7). However, separating triggering earthquakes from others is difficult. Ogata (1988) generalized this model by removing the distinguishment between triggering events and the other events. Each event, irrespective of whether it is a small or large event, can, in principle, trigger its own aftershocks. This model incorporates the Omori-Utsu formula into the Hawkes self-exciting process.

More precisely, the temporal conditional intensity of this model is:

$$\lambda(t) = \mu + \sum_{i: t_i < t} \kappa(m_i) g(t - t_i), \quad (43)$$

where $s(m) = \beta e^{-\beta(m-m_0)}$, $m \geq m_0$ is the PDF form of the Gutenberg-Richter relation, in which m_0 is the magnitude threshold, $\kappa(m) = A \exp[\alpha(m - m_0)]$ is the mean number of events directly triggered by an event of magnitude m , and $g(u) = (p - 1)(1 + t/c)^{-p}/c$ is the probability density function (p. d. f.) of the time difference between the parent event and its child, i.e., the p.d.f. form of the Omori-Utsu formula. Ogata (1988) termed (43) the ETAS model based on an analogy with the spread of epidemics. The magnitude of an aftershock does not have to be smaller than its parent in the ETAS model. The ETAS model also belongs to a more general class of self-exciting Hawkes processes (1971).

A condition for the stability of the ETAS model is that the process must be subcritical. In data analysis, this important condition justifies whether the estimated model parameters are reasonable or irrational. For the ETAS model, the critical parameter is as follows:

$$\varrho = \int_{m_0}^{\infty} s(m) \kappa(m) dm = \frac{A\beta}{\beta - \alpha}.$$

When $\varrho < 1$, the ETAS model is stable and stationary, which requires $\beta \geq \alpha$ and $A \leq 1 - \alpha/\beta$. When $\varrho \geq 1$, there is a finite probability that the number of events in a unit time interval becomes infinite as t increases to infinity. Zhuang and Ogata (2006) discuss more details on the behavior of the ETAS model.

Simulation, Forecasting, and Performance Evaluation

Generic Simulation Method for Temporal Point Processes

Simulations allow for the visualization of a statistical model. In comparison, one can obtain ideas of how to improve the model based on the difference between the simulated catalog and real seismicity. Seismicity models specified by the conditional intensity can be simulated by at least two methods: one is the inversion method and the other is the thinning method.

The inversion method uses the relationship between the conditional intensity function and hazard function, i.e., $\lambda(t + \tau) = h_t(\tau)$, $\tau \geq 0$, and the relation between the hazard function and probability distribution function:

$$h_t(\tau) = -\frac{d}{d\tau} [\log(1 - F_t(\tau))]. \quad (44)$$

The waiting time, W , to the next event from the current time, t , can be obtained by solving for W in:

$$U = 1 - F_t(W) = \exp \left[- \int_t^{t+W} \lambda(v) dv \right],$$

where U is a uniform random variable on $[0, 1]$.

Ogata (1981) introduced the thinning method to simulate a temporal point process, N , described by a bounded conditional intensity, $\lambda(t)$. Daley and Vere-Jones (2003) modified this method for the case where $\lambda(t)$ increases boundlessly between events (such as the stress release model). A concise proof of the thinning method is provided in Zhuang and Touati (2015). This algorithm is outlined below:

If we simulate a temporal point process, N , equipped with a conditional intensity, $\lambda(t)$, in the time interval $[t_{\text{start}}, t_{\text{end}}]$, then we have the following:

- Step 1. Set $t = t_{\text{start}}$ and $i = 0$.
- Step 2. Select a positive number, $\Delta \leq t_{\text{end}} - t$, and find a positive M such that $\lambda(t) < M$ on $[t, t + \Delta]$ under the condition that no event occurs on $[t, t + \Delta]$.
- Step 3. Simulate the waiting time, τ , according to a Poisson process of rate M , i.e., $\tau \sim \text{Exp}(M)$.
- Step 4. Generate a random variate, $U \sim \text{uniform}(0, 1)$.

- Step 5. If $U \leq \lambda(t + \tau)/M$ and $\tau < \Delta$, set $t_{i+1} = t + \tau$, $t = t + \tau$, and $i = i + 1$. Otherwise, set $t = t + \min(\tau, \Delta)$, i.e., rejecting the event and progressing with time.
- Step 6. Return to step 2 if t does not exceed t_{end} .
- Step 7. Return $\{t_1, t_2, \dots, t_n\}$, where n is a sequential number from the last event.

Probability Forecasts and Performance Evaluation

Another direct use of simulation is forecasting. Vere-Jones (1998) provides a standard scheme for earthquake probability forecasting based on random simulations, relating the scoring procedure for evaluating the forecasting performance. The conditional intensity is natural for forecasting. Given observations in the past and future, the model parameters in the conditional intensity function can be obtained by fitting the model to the past observations. Once the model parameters are obtained, the occurrence process of the events in the given future interval can be simulated according to the conditional intensity and past observations. The forecasting probability can then be estimated based on

$$\Pr\{\text{phenomenon } A \text{ occurs}\} \approx \frac{\text{number of simulations in which } A \text{ occurs}}{\text{total number of simulations}}. \quad (45)$$

The evaluation of the performance of such forecasts can be performed in a measured and statistical manner using the framework of probability gain or information gain. First, a reference model is selected, usually the Poisson model. Suppose that for a future space-time-magnitude cell, the probability that an earthquake with a target magnitude occurs within it is $p^{(0)}$ according to the reference model, where p is given by the forecasting model. The probability of this forecast is:

$$p_g = X \frac{p}{p^{(0)}} + (1 - X) \frac{1 - p}{1 - p^{(0)}}, \quad (46)$$

and the information gain is as follows:

$$I_g = \log p_g, \quad (47)$$

where $X = 1$ if the target event occurs; otherwise, $X = 0$. Such an information gain can be summed over many forecast intervals:

$$I_g = \sum_{i=1}^K \left[X_i \log \frac{p_i}{p_i^{(0)}} + (1 - X_i) \log \frac{1 - p_i}{1 - p_i^{(0)}} \right], \quad (48)$$

where $p_i, p_i^{(0)}$ and $i = 1, 2, \dots, K$, are the probabilities of event occurrence based on the forecasting and reference models, respectively. The average information gain per cell and the

average information per event, defined by I_g/K and I_g/N , where K is the total number of cells over which to forecast and N is the total actual number of events occurring in the forecasting space-time-magnitude range, are often used as measures of the forecasting performance.

Episode III: Advanced Models, Modelling Techniques and Applications in Forecasting and Testing

This stage began in the late 1990s. First, models were extended for more complicated and high-dimensional cases. The stress-released model was extended to the linked (coupled) stress release model (e.g., Bebbington and Harte 2003), which is used for long-term seismic hazard estimation. The ETAS model has also been extensively examined and widely used for analyzing seismicity data. Ogata (1998) extended this model to a space-time form while Zhuang et al. (2002) proposed the ETAS model-based method for declustering an earthquake catalog, referred to as the stochastic declustering method. During this period, the importance of statistical seismology was also recognized by seismologists. An increasing number of seismologists accepted that the ETAS model should be the null hypothesis for testing hypotheses related to seismicity patterns, replacing the Poisson model (complete randomness). Another feature of the research conducted during this period was that the rate- and state-dependent friction laws were incorporated with the ETAS model to explain different phenomena in microseismicity. Additionally, rigorous statistical testing methods for earthquake forecasting were also developed. The international project ‘‘Collaboratory for Studies of Earthquake Predictability (CSEP)’’ was established by the Southern California Earthquake Center, performing rigorous statistical testing for submitted earthquake forecasting methods. Japan, Europe, New Zealand, and China also installed their own CSEP projects.

Developments Related to Stress Release Models

The linked stress release model is an extension of the univariate stress release model (e.g., Bebbington and Harte (2003)). This model considers the stress transfer and interaction between several regions. Assume that we have k tectonic subregions. The evolution of stress can be written as:

$$X_i(t) = X_i(0) + \rho_i t - \sum_{j=1}^k c_{ij} S^{(j)}(t). \quad (49)$$

For each subregion i , $S^{(j)}(t)$ is the accumulated stress released in region j over the period $(0, t)$, and the coefficient c_{ij} measures the fixed proportion of the stress drop that occurs

in region j that is transferred to region i . If $c_{ij} = 0$ for the case where $i \neq j$, this model can be reduced to the simple stress release model in each subregion. Identical to the simple stress release model, the risk in each subregion is assumed to depend exponentially on the stress, i.e., the conditional intensity takes the following form:

$$\begin{aligned}\lambda_i(t) &= \exp[\mu_i + v_i X_i(t)] \\ &= \exp\left\{a_i + b_i t - \sum_{j=1}^k C_{ij} S^{(j)}(t)\right\},\end{aligned}\quad (50)$$

where $a_i (= \mu_i + v_i X_i(0))$, $b_i = v_i \rho_i$, and $C_{ij} = v_i c_{ij}$ are the model parameters to be estimated.

ETAS Model: From Temporal to Spatiotemporal

Formulation

Not many spatiotemporal models describe seismicity. One reason is that complicated numerical computations are always involved in the implementation. Among the few spatiotemporal models that have been proposed, only the spatiotemporal ETAS model has been extensively used and widely accepted as the standard model in the context of short-term earthquake clustering. Mathematically, this model is in the class of marked branching processes with immigration. This subsection focuses on issues related to spatiotemporal ETAS models, such as the estimation of the background rate, stochastic declustering, and stochastic reconstruction, among others.

Before Ogata generalized the temporal ETAS model to a space-time version, Musmeci and Vere-Jones (1992) used space-time diffusion clustering models to analyze the seismicity in Italy. Conditional intensity functions for these models are the:

$$\lambda(t, x, y, M) = \mu(x, y) + A \sum_{t_i < t} \frac{e^{\alpha M_i} e^{-c(t-t_i)}}{2\pi\sigma_x\sigma_y t} \exp\left\{-\frac{1}{2t} \left(\frac{x^2}{\sigma_x^2} + \frac{y^2}{\sigma_y^2}\right)\right\}, \quad (51)$$

and

$$\begin{aligned}\lambda(t, x, y, M) &= \mu(x, y) \\ &+ \frac{A e^{\alpha M} e^{-ct} t^2 C_x C_y}{\pi^2 (x^2 + t^2 C_x^2) (y^2 + t^2 C_y^2)},\end{aligned}\quad (52)$$

where A , α , σ_x , σ_y , C_x , and C_y are constants. For a fixed point (x, y) , when $t \rightarrow \infty$, the aftershocks in (51) and (52) decay with time according to $t^{-1}e^{-ct}$ and $t^{-2}e^{-ct}$, respectively.

Ogata (1998) used the following conditional intensity, which is generally used at present for the space-time ETAS model:

$$\begin{aligned}\lambda(t, x, y) &= \mu(x, y) \\ &+ \sum_{i: t_i < t} \kappa(m_i) g(t - t_i) f(x - x_i, y - y_i; m_i),\end{aligned}\quad (53)$$

where:

$$\kappa(m) = A e^{\alpha(m-m_0)} \quad (54)$$

is the expected number of aftershocks generated from a mainshock of magnitude M ,

$$g(t) = \begin{cases} (p-1)c^{p-1}(t+c)^{-p}, & \text{for } t > 0, \\ 0, & \text{otherwise,} \end{cases} \quad (55)$$

is a probability density function of the lagged time distribution of aftershocks, derived from the Omori-Utsu formula:

$$f(x, y; m) = \frac{1}{\pi\sigma(m)} f_0\left(\frac{x^2 + y^2}{\sigma(m)}\right) \quad (56)$$

is the density function of the aftershock locations from a mainshock at the origin with magnitude m . Different functions have been used for $f_0(x, y)$ and $\sigma(m)$. Usually, f_0 has a 2D gaussian density, i.e., $f_0(\omega) = \frac{1}{2D^2} e^{-\frac{\omega^2}{2D^2}}$, or inverse power, i.e., $f_0(\omega) = \frac{q-1}{D^2} \left(1 + \frac{\omega^2}{D^2}\right)^{-q}$, and $\sigma(m) \propto \kappa(m)$ or $\sigma(m) \propto [\kappa(m)]^{\frac{1}{2}}$, where D , q , and γ are extra model parameters. As shown in Zhuang et al. (2004), the inverse power form of f_0 and $\sigma(m) \propto [\kappa(m)]^{\frac{1}{2}}$ usually fit earthquake data better than other forms. Anisotropic response functions, i.e., replacing $\frac{1}{1-\rho^2} (vx^2 + 2\rho xy + y^2/v)$ with $x^2 + y^2$ in (56), have also been used to model the anisotropic shape of aftershock zones (e.g., Ogata and Zhuang 2006).

Stochastic Declustering

The proportion of the contribution from event i at the occurrence of (t_j, x_j, y_j) is as follows:

$$\rho_{ij} = \begin{cases} \frac{\xi(t_j, x_j, y_j; t_i, x_i, y_i)}{\lambda(t_j, x_j, y_j)}, & \text{when } j > i, \\ 0, & \text{otherwise.} \end{cases} \quad (57)$$

This quantity can be explained as the probability that event j is triggered by the i th event. Moreover, the probability that the j th event belongs to the background is:

$$\varphi_j = \frac{\mu(x_j, y_j)}{\lambda(t_j, x_j, y_j)}. \quad (58)$$

If we select each event, j , with probabilities ρ_{ij} or φ_j , we can form a new process consisting of the events triggered by the i th event or a new process consisting of the background events, respectively.

The above algorithm resolves the difficulties in testing hypotheses associated with earthquake clustering features, which are caused by the complicated mixture of the background seismicity and different earthquake clusters in both space and time. Different stochastic versions separate the earthquake clusters by repeating the stochastic declustering procedure for an extended period. The nonuniqueness of such realizations is an advantage of stochastic declustering as it illustrates the uncertainty in determining earthquake clusters; thus, repetition can aid in the evaluation of the significance of some properties of seismic clustering patterns. However, we can also implement these tests by directly using the probabilities, i.e., φ_j and ρ_{ij} . For example, Zhuang et al. (2005) defined the cumulative background seismicity in a certain region

$$S(t) = \sum_{i:t_i < t} \varphi_i. \quad (59)$$

This function can be used to verify whether the background seismicity in a region is stationary or not.

Estimation of Space-Time ETAS Model

Given an earthquake catalog, Zhuang et al. (2002) proposed an algorithm to estimate the model parameters and nonparametric background rate in the space-time ETAS model by iterating the following steps.

- Given some background rate, μ , we can maximize the likelihood function:

$$\begin{aligned} \log L(\theta) = & \sum_{i:t_i \in [0, T], (x_i, y_i) \in S} \log \lambda_{\theta}(t_{ki}, x_{ki}, y_{ik}) \\ & - \int_0^T \int_S \lambda_{\theta}(t, x, y) dx dy dt, \end{aligned} \quad (60)$$

where:

$$\begin{aligned} \lambda(t, x, y) = & \nu \mu(x, y) \\ & + \sum_{i:t_i < t} \kappa(M_i) g(t - t_i) f(x - x_i, y - y_i; M_i). \end{aligned} \quad (61)$$

- Calculate $\varphi_i = \frac{\mu(x_i, y_i)}{\lambda(t_i, x_i, y_i)}$ for i across all of the events.

- Obtain an improved estimation of $\mu(x, y)$. For example, Zhuang et al. (2002) used the weighted variable kernel estimate:

$$\hat{\mu}(x, y) = \frac{1}{T} \sum_i \varphi_i K(x - x_i, y - y_i, h_i), \quad (62)$$

where $K(x, y, h)$ is a 2D Gaussian kernel function with bandwidth h and the variable bandwidth, h_i , is the distance from the i th event to its n_p closest neighboring event or a fixed value if this distance is smaller than it; n_p usually ranging from 3 to 6.

This algorithm has been further developed as nonparametric estimates of the earthquake clustering model or the more complicated Hawkes models.

Simulation of the ETAS Model

Instead of using the generic inversion or thinning method, the simulation of the space-time ETAS model can be implemented based on its natural branching structure (Zhuang et al. 2004; Zhuang and Touati 2015). Suppose that we have observations, $\{(t_i, m_i) : i = 1, 2, \dots, K\}$, up to time t_{start} with the objective of forward simulating the process along time interval $[t_{\text{start}}, t_{\text{end}}]$.

Step 1. Generate a background catalog as a stationary Poisson process with the estimated background intensity, μ , on $[t_{\text{start}}, t_{\text{end}}]$, together with the original observations, $\{(t_i, m_i) : i = 1, 2, \dots, K\}$, before t_{start} , recorded as Generation 0, i.e., $G^{(0)}$.

Step 2. Set $P = 0$.

Step 3. For each event i , i.e., (t_i, m_i) , in the catalog, $G^{(\ell)}$, simulate its $N_i^{(\ell)}$ offspring: $O_i^{(\ell)} = \{(t_k^{(i)}, m_k^{(i)}) : i = 1, 2, \dots, N_i^{(\ell)}\}$, where $N_i^{(\ell)}$ is a Poisson random variable with a mean of $\kappa(m_i) t_k^{(i)}$ is generated from the probability density, $g(t - t_i)$, and $m_k^{(i)}$ is generated according to the methods described in Sect. 4.

Step 4. Set $G^{(\ell+1)} = \cup_{i \in G^{(\ell)}} O_i^{(\ell)}$.

Step 5. Remove all events whose occurrence times are after t_{end} from $G^{(\ell+1)}$.

Step 6. If $G^{(\ell+1)}$ is not empty, let $\ell = \ell + 1$ and return to Step 3; otherwise, return $\cup_{j=0}^{\ell} G^{(j)}$.

The above algorithm is computationally more efficient (and thus quicker), as the sum over past events is only performed within a single aftershock cascade for each simulated event, not over the entire history, as in the first method. This also allows events to be labelled so as to indicate their position in the branching process, such that the “family tree”

information of a background event and multiple generations of aftershocks are preserved and available for analysis.

Applications of the ETAS Model

Many interesting topics have attracted the attention of statistical seismologists.

The Båth Law

The first topic is the relation between the ETAS model and *Båth's law*. Båth's law (1965) suggests that the median magnitude difference between the a mainshock and its largest aftershock is approximately 1.2. Utsu (1957) expressed the median of this difference as a linear function of the mainshock magnitude. Many studies have shown that Båth's law can be explained as a double exponential distribution generated by the ETAS model (e.g., Luo and Zhuang (2016)).

Testing the Foreshock Hypothesis

Seismologists have extensively examined whether foreshocks can be explained by a clustering model for aftershocks, i.e., whether foreshocks are mainshocks whose aftershocks happen to be bigger. Several researchers have suggested that the probability of foreshock phenomena does not exceed the probability of a foreshock expected by an ETAS-like generic clustering model (e.g., Saichev and Sornette (2005) and Zhuang and Ogata (2006)). Many simulation studies have been conducted by different researchers; however, unlike the conclusions for Båth's law, the conclusions diverge.

Induced Seismicity

Induced seismicity caused by human activities, such as waste fluid disposal and reservoir impoundment, has attracted public attention and scientific interest. The ETAS model has been applied to this area to quantify the difference between induced seismicity and natural earthquakes, as well as to provide an assessment of related seismic hazards (Lei et al. 2008; Llenos and Michael 2013).

ETAS Model and the Rate-and-State Friction Law

The ETAS model can be used to detect the change point in the total seismicity rate through a transformed time sequence-based residual analysis (Ogata 1988, or in The background seismicity rate (Zhuang et al. 2005). The rate-and-state dependent fraction law has been used to explain such changes (e.g., Jia et al. 2014).

Further Extension and Recent Developments of the Space-Time ETAS Model

Impact of Anisotropy of Earthquake Clusters and Hypocenter Depth

Aftershock clusters of larger mainshocks are usually not isotropic around the epicenter of the mainshock but are rather

aligned along the mainshock rupture. Hainzl et al. (2008) demonstrated via ETAS simulations that ignoring this fact can lead to a biased parameter estimation, particularly to an underestimation of the (ν parameter). To account for anisotropy, (Ogata 1998) used an elliptical aftershock distribution. Recently, Guo et al. (2015b) developed a finite-source ETAS model that considers the influence that the rupture geometry of large earthquakes has on the aftershock locations. In the model formulation, for an earthquake that has a finite source with a projection area, S , on Earth's surface, the spatial response is modified as follows:

$$f(x, y; S) = \frac{\iint_S f(x-u, y-v) \tau(u, v) du dv}{\iint_S \tau(u, v) du dv} \quad (63)$$

where (u, v) is a location on S and $\tau(u, v)$ is the inhomogeneous productivity density of the mainshock along the rupture area, where the integral in the denominator is for normalization. Guo et al. (2015a) also developed a 3D ETAS model to incorporate the hypocenter depth in the model formulation, where the spatial response is as follows:

$$f(x, y, z; m_i, z_i) = f(x, y; m_i) h(z, z_i) \quad (64)$$

where $f(x, y; m_i) = \frac{q-1}{\pi D'^2} \left(1 + \frac{x^2+y^2}{D'^2}\right)$, where D' is a newly introduced parameter defined as follows:

$$h(z, z_i) = \frac{\left(\frac{z}{H}\right)^{\eta_H} \left(1 - \frac{z}{H}\right)^{\eta(1-\frac{z}{H})}}{HB \left(\eta \frac{z}{H} + 1, \eta \left(1 - \frac{z}{H}\right) + 1\right)} \quad (65)$$

where B is the beta function, $B(p, q) = \int_0^1 t^{p-1} (1-t)^{q-1} dt$, t , and H is the maximum depth. Zhuang et al. (2019) showed that the 3D and finite-source ETAS models performed better than the 2D point source ETAS model when fitting them to the Italian catalog.

Location-Dependent ETAS Parameters

Ogata (2004) developed a hierarchical space-time ETAS model to describe the difference in the seismicity clustering structure at different locations. Ogata (2004) assumed that each parameter in the model is a function of location, which has a smoothness prior. Ogata (2004) developed powerful Bayesian tools with penalized likelihoods to estimate the changes in the clustering characteristics in the form of spatial variation in the model parameters. Zhuang (2015) developed the weighted likelihood method to estimate the spatial variations in the space-time ETAS model, applying it to the seismicity of Japan.

Self-Similar ETAS Models

Vere-Jones (2005) developed a self-similar ETAS model to avoid problems caused by the cutoff magnitude in the ETAS model and enable fully self-similar features. Owing to the missing data problem for immediate after-shocks and small events; however, this model remains theoretically underdeveloped and has not yet been applied to actual seismicity data. Another development in self-similarity has been the introduction of the branching after-shock sequence (BASS) model (e.g., Turcotte et al. 2007). However, such an extension cannot be successful as the Gutenberg-Richter magnitude frequency relationship owing to the destruction of all of the events in the process (see Zhuang et al. 2013).

Other Space-Time Models: The EEPAS and Double Branching Models

The EEPAS (Every Earthquake is a Precursor According to Scale) model was developed by Evison and Rhoades (2004) and Rhoades and Evison (2004) in their studies on foreshock swarms. Its conditional intensity is as follows:

$$\lambda(t, x, y, m) = \mu\lambda_0(t, x, y, m) + \sum_{i:t_i < t} w_i \eta(m_i) r(m|m_i) f(t-t_i) g(x-x_i, y-y_i|m_i), \quad (66)$$

where f , g , and r are normal or lognormal densities, i.e.:

$$f(u|m_i) = \frac{1}{u\sigma_T\sqrt{2\pi}} \exp\left[-\frac{(\log u - a_T - b_T m_i)^2}{2\sigma_T^2}\right], \quad (67)$$

$$g(x, y|m_i) = \frac{1}{2\pi\sigma_A^2 10^{m_i b_A}} \exp\left[-\frac{x^2 + y^2}{2\sigma_A^2 10^{m_i b_A}}\right], \quad (68)$$

$$r(m|m_i) = \frac{1}{\sigma_M\sqrt{2\pi}} \exp\left[-\frac{(m - a_T - b_T m_i)^2}{2\sigma_M^2}\right] C \quad (69)$$

The weights, w_i , are usually set to one, but they can be also set according to the probability of being a background event, which is obtained from an initial stochastic declustering *REJECT* using the ETAS model. This model has a similar form as the ETAS model but is different in detail. The conditional intensity function is not applied to the entire catalog, but only for events above a second higher threshold while the summation is performed for all of the events above a primary lower threshold. This model appears to produce high average probability gains or entropy scores for moderate-term forecasts of medium to large events. Here, we refer to Rhoades and Evison (2004) for detailed applications.

Marzocchi and Lombardi (2008) proposed the double-branching model, where the triggering between earthquakes can be divided into two steps: one is short-term clustering owing to the elastic response in the upper layers of Earth, which can be well represented by the ETAS model, and the other is the interaction among events over longer time-space scales. The conditional intensity of this model has the following form:

$$\lambda(t, x, y) = \mu_2(x, y) + \sum_{i:t_i < t} \left[\frac{K_1 e^{\alpha_1(M_i - M_0)}}{(t - t_i + c)^p} \frac{C_1}{r_i^2 + d_1^2} \right] + \sum_{i:t_i < t} \left[K_2 e^{\alpha_2(M_i - M_0)} e^{-(t-t_i)/\tau} \frac{C_2}{r_i^2 + d_2^2} \right]$$

where K_1 , K_2 , α_1 , α_2 , c , p , τ , d_1 , d_2 , q_1 , and q_2 are model parameters, and C_1 and C_2 are normalization constants. Marzocchi and Lombardi (2008) used a two-step approach to estimate this model: They first used Algorithm A to obtain the background probabilities based on the stochastic declustering method, followed by fitting a self-exciting model with the second summation term in Eq. (70) to the catalog of background events. They found that the background seismicity, obtained by removing short-term clustering, is characterized by a second-step long-term clustering with a characteristic time compatible with post-seismic relaxation.

Conclusion and Future Prospects

As a subject that aims to bridge the gap between physical and statistical models, statistical seismology has developed rapidly during the last several decades. A significant achievement is the formulation of conditional intensity models for quantifying time-varying seismicity rates. The conditional intensity is natural for forecasting and the evaluation of the forecasting performance can be completed in a measured and statistical manner using the probability gain framework. The ETAS model has especially become a de facto standard model, or null hypotheses, for comparison with other models and ideas. This suggests that improvements to our understanding of earthquake clustering can be quantified by developing new ideas into models and then comparing them to ETAS, or other models, using statistical hypothesis testing. Ultimately, the rigorous testing of forecast models is necessary to improve our ability to forecast seismic hazards.

Currently, owing to our inability to observe many of the fundamental processes of the system, as well as its inherent randomness, it is difficult to deterministically predict individual earthquakes. Therefore, statistical seismology, which places a larger focus on probabilistic forecasting, represents the best quantification method with respect to our state of

knowledge. Furthermore, to provide more reliable earthquake forecast models, the challenge becomes the construction of models that can yield increased information gain with respect to a reference model, such as ETAS or complete randomness.

With the rapid development of observation technologies, an increasing amount of observational data has been obtained. These new observations provide new theories and approaches to help us understand seismicity. Based on these new observations, seismologists can develop new methods to more efficiently analyze these data and new models to connect them to the earthquake process and tectonic environments, thus providing more knowledge on the earthquake occurrence process and the ability to obtain reliable forecasts.

Stereographic Projections

Frits Agterberg

Central Canada Division, Geomathematics Section,
Geological Survey of Canada, Ottawa, ON, Canada

Definition

Stereographic projections are geometrical mapping functions to project a sphere that contains directional features of interest onto a plane. This type of mapping is either conformal in that it preserves the angles at which different curves meet or it is area-preserving in that two sectors with the same area on the sphere have the same areas after two-dimensional projection. Both types of projections are often used in geosciences. In this chapter the emphasis will be on directed or undirected linear features that are subject to significant uncertainty. Such features can provide important information, especially in paleomagnetism and in structural geology. The differences between conformal and area-preserving projections are important in applications of remote sensing and geomatics (topographic map-making) but less important in geosciences for mapping features with significant directional uncertainties.

Introduction

Two types of graph paper associated with informal and area-preserving mapping, respectively, are known as Wulff net and Schmidt net. George Wulff (1902) was a Russian mineralogist and Adolf Schmidt was a German geophysicist (cf. Bartels 1947). Comprehensive reviews of hemisphere partition into cells with projections onto the plane can be found in Beckers and Beckers (2012) and Snyder (1993).

In a 3D space, the unit sphere is a set of points (x, y, z) with the property $x^2 + y^2 + z^2 = 1$. Using Cartesian coordinates (x, y, z) for points on the sphere and (X, Y) for the corresponding points on the plane with $z = 0$, the projection and its inverse are given by the equations:

$$(X, Y) = \left(\frac{x}{1-z}, \frac{y}{1-z} \right); \quad (x, y, z) \\ = \left(\frac{2X}{1+X^2+Y^2}, \frac{2Y}{1+X^2+Y^2}, \frac{X^2+Y^2-1}{1+X^2+Y^2} \right).$$

An alternative formulation of this result is obtained by using spherical coordinates (ϕ, θ) on the sphere where the angle ϕ (with $0 \leq \phi \leq \pi$) has azimuth θ ($0 \leq \theta \leq 2\pi$). With polar coordinates (R, Θ) on the plane, the projection and its inverse become:

$$(R, \Theta) = \left(\frac{\sin \varphi}{1 - \cos \phi}, \theta \right) = (\cot \varphi/2, \theta); \quad (\phi, \theta) = s.$$

Because of closure of the system, $\phi = \pi$ when $R = 0$. Several other conventions for this type of projection have been developed (see e.g., Gelfand et al. 1963).

Wulff Net

The required calculations introduced in the previous section can be carried out by computer, but, in geoscientific applications, it has become a common practice to use the Wulff net that is the stereographic projection of the grid of parallels and meridians on the bottom half of the sphere centered at a point on the equator. The images of the parallels and meridians on the Wulff net intersect one another at right angles. Any plane in three-dimensional space is characterized by its pole that passes through the origin and is perpendicular to the plane, which becomes a single uniquely defined point on its stereographic projection.

Further discussion and examples of Wulff net applications are provided in Agterberg (1961), a book that can be freely downloaded from the Internet by typing in its title. In a section on unit vectors in space (Agterberg 1974, Fig. 106, adapted from Whitten 1966), the use of the Wulff net is illustrated by using minor fold axes at 35 different localities in Paleozoic quartz phyllites near Monguelfo, Northern Italy. The vector mean of these directional features was also calculated. It dips 54° to the east and is shown in two Wulff net diagrams (Agterberg 1961, Figs. 17 and 18). The first of these two plots shows five cones (with top angles of 6° , 12° , 18° , 24° , and 30°) with the mean unit vector as their common axis. These five cones plot as circles. Together, they depict a so-called Fisher distribution (cf. Fisher 1953) that for small values of the standard deviation σ of deviations from the mean cannot be distinguished from an isotropic two-dimensional normal distribution (cf. Agterberg 1974, Sect. 14.3). In structural geology (cf. Ramsay 1967), it is common practice to contour frequency distributions of this type on the Wulff net (and also on the Schmidt net discussed in next section) by moving a small unit circle (e.g., 1% of total hemisphere area) across the net and counting the number of points it contains. For the 35 minor folds of the Monguelfo example, the resulting contour pattern (Agterberg 1961, Fig. 18) is a conical plot.

Schmitt Net

Formally, the Schmitt net is a manual drafting method for the Lambert azimuthal equal-area projection using graph paper.

Worldwide, it results in a lateral hemisphere of the Earth with its grid of parallels and meridians. The theory of hemispherical partition into equal area cells is covered in detail by Beckers and Beckers (2012). This type of plot is widely used in geophysics (especially paleomagnetism) and structural geology (Ramsay 1967; Borradaile 2003). An advantage of the Schmitt net with respect to the Wulff net is that it preserves areas. For example, two circular areas on the sphere project as two circles with the same area when the Schmitt net is used but their areas are slightly different on the Wulff net. In most geophysical and structural geologic applications, this difference in properties between the Wulff net and the Schmitt net is of no consequence. The following example after Agterberg (1985) illustrates the use of the Schmitt net in structural geology.

Figure 1 is a structure map of strongly deformed Paleozoic quartz phyllites in the San Stefano area to the east of the Dolomites in northern Italy. These quartz phyllites form the core of a later formed (Alpine) anticlinal structure. Sedimentary rocks to the northeast and southwest of the anticlinal core dip to the northeast and southwest, respectively. They are Permian in age commencing with the Permian Verrucano conglomerate that contains boulders of the Paleozoic quartz phyllites showing schistosity and minor folds similar to those found in the core of the Alpine San Stefano anticline proving that the schistosity and minor folds predated the Alpine orogeny.

Various methods of unit vector field analysis have been developed using the Alpine San Stefano anticline for testing purposes. These include two-dimensional polynomial trend-surface fitting applied separately to the three direction cosines of the measurements on minor fold axes in the outcrops shown as black dots in Fig. 1 followed by combining the estimated values to construct a unit vector field. Mathematical derivation of the underlying theory was presented in Agterberg (2012). Another approach to solve the same problem was based on fitting Fisher distributions on directional features in relatively large overlapping areas (Agterberg 1985). These later, more sophisticated methods essentially confirmed the results shown in Fig. 1 that were originally obtained using relatively simple statistical methods.

The San Stefano quartz phyllite is a soft rock that is only locally exposed, essentially along streams. Its outcrops are of two types: almost everywhere Hercynian minor folds are clearly exposed, and their azimuths and dips can be measured. However, only in relatively few outcrops can the strike and dip of the Hercynian schistosity for the entire outcrop be measured as well, because frequently it too strongly folded to determine its average attitude. Schmidt net plots for the two circular areas (A and B) in Fig. 1 are shown in Fig. 2. The mean schistosity attitudes for these two subareas (with strikes and dips shown in Fig. 1 and as $\square$ in Fig. 2) are similar, although they are based on relatively few individual

Stereographic Projections, Fig. 1 Preferred attitudes of schistosity planes and B-lineations with extrapolated regional pattern for crystalline basement of eastern Dolomites near San Stefano (after Agterberg 1961).

observations (shown as ○). The average minor fold axes are shown as arrows along with their angles of dip in Fig. 1. As shown in Fig. 2, they are more abundant than the schistosity plane measurements. Their 1% contours of total hemisphere area are shown on these two Schmitt net projections.

During Alpine orogeny, the San Stefano crystalline formed the core of an anticline in which movements along the Hercynian schistosity planes were reactivated. The trace of the resulting Alpine NW-SE trending axial plane intersects the approximately WNW-ESE striking Hercynian schistosity planes (Fig. 1). This style of folding is analogous to that described earlier by Ramsay (1967) for gneisses at Arnisdale, western Highlands of Scotland of which an example is shown in Fig. 3 where the pattern is for the azimuths of deformed B-lineations. Axial traces (intersections of axial planes with the topographic surface) for the later folds are indicated clearly in Fig. 3. The patterns of this type can become almost completely obscured when the surfaces, on which the

Cells of 100 m on a side, where one or more B-lineations were measured, are shown by dots. Domains for Fig. 2 are indicated by circles (A and B). (Source: Agterberg 1974, Fig. 110)

lineation was developed, were themselves variably oriented or when the amount of compressive strain accompanying the original folding was variable in space as in the San Stefano example of Figs. 1 and 2.

Summary and Conclusions

Two-dimensional stereographic projections of features on the sphere are either conformal preserving the angles at which different curves meet, or they are area-preserving in that two sectors with the same area on the sphere have the same areas after stereographic projection. The differences between conformal and area-preserving projections are important in applications of remote sensing and geomatics (topographic map-making) but less important in the geosciences for mapping features with significant directional uncertainties as are encountered in geophysics and structural geology. Properties

Stereographic Projections,

Fig. 2 Lineations (dots) and *s*-poles (circles) plotted on equal-area Schmidt nets, lower hemisphere, for domains A and B in central part of Fig. 1. For further explanations, see text (Source: Agterberg 1974, Fig. 111)

of the Wulff net and the Schmidt net were summarized in this chapter. The example discussed in detail was deciphering repeated movement of mass along schistosity planes during Hercynian and Alpine orogenies in the San Stefano quartz phyllite east of the Dolomites in North Italy.

Stereology

Leszek Wojnar
Krakow University of Technology, Krakow, Poland

Roots and Definition

For the first time the word stereology was coined on May 11, 1961 during an informal meeting on Feldberg Mountain in the Black Forest, Germany. It was a result of discussion on invention of a single word describing three-dimensional (3D) interpretation of flat images, such as sections and projections (Underwood 1987). Soon, the International Society for Stereology, currently International Society for Stereology and Image Analysis, was founded.

One of the first definitions has expressed stereology as a body of procedures, mainly geometrico-statistical, which has the aim of obtaining information about three-dimensional structure from two-dimensional, flat images. It could also be defined as extrapolation from two- to three-dimensional space (Weibel 1987). Surprisingly, this old definition seems to be the most adequate to nowadays times.

In the monograph by Hilliard and Lawson (2003) one can find introductory remarks starting with a sentence which is very important for geosciences: Stereology began with the examination of rocks. The authors know the problem of precise definition of stereology and dynamic changes within

it: “The problem of defining stereology is existential: since existence precedes essence, we will not know exactly what stereology is until stereology is dead; then we will know what stereology was” (Hilliard and Lawson 2003).

The abovementioned monograph informs about 21 separate definitions for stereology. It is too much for analysis in a short chapter, so the review has to be limited. Currently at least four different definitions can be found at the top of the Internet browsers, the most popular and easily accessible source of information:

- Stereology is a branch of science concerned with inferring the three-dimensional properties of objects or matter ordinarily observed two-dimensionally (Stereology 2020b).
- Stereology is the three-dimensional interpretation of two-dimensional cross sections of materials or tissues. It provides practical techniques for extracting quantitative information about a three-dimensional material from measurements made on two-dimensional planar sections of the material (Stereology 2020a).
- Stereology is the process of sampling and counting material using specific protocols to obtain an estimate of a quantitative parameter, such as number, length, volume, etc. Obtaining accurate estimates is a critical component of producing a study outcome with statistical validity. By using appropriate sampling procedures and applying counting or measuring protocols (known as probes), stereology makes it possible to avoid potential artifacts and errors that could significantly skew results (Peterson 2020).
- Even the International Society for Stereology and Image Analysis gives a definition which is far from precision and completeness: It is an interdisciplinary field that is largely concerned with the three-dimensional interpretation of planar sections of materials or tissues. It provides practical techniques for extracting quantitative information about a three-dimensional material from measurements made on two-dimensional planar sections of the material (ISSIA 2020).

From the above-listed definitions it is difficult to find close relation to modern techniques based on computer-aided image analysis and/or tomography. Each of these definitions is generally correct but none of them seems to be complete. In spite of the passage of time clear explanation of the borders of stereology, which have significantly widened, is still problematic. Equipment for automatic image analysis was commercialized several years after introduction of stereology. Consequently, stereology has dealt initially only with manual methods which are very laborious and time consuming. As a result, many researchers and practitioners recognize stereology as an outdated tool, not applicable to modern, computerized, and often automated methods.

Stereology, Fig. 1 Three-dimensional structure with its projection (objects marked in blue) and exemplary section (objects marked in red)
(Source: Wojnar L (2020))

Contemporary stereology can be defined in the following words:

Stereology is an interdisciplinary branch of science comprising theoretical background, rules, and procedures for quantitative characterization of geometrical properties of real or virtual objects detectable in any kind of images. The most traditional task of stereological analysis is three-dimensional interpretation of flat images, being sections or projections of the examined structures (see Fig. 1).

Scope and Limitations

Classical methods of stereology are applicable to virtually any types of objects in 3D space, like particles of various minerals, fibers, edges, pores, fracture surfaces, etc. Nevertheless, in contrast to tomography, which can effectively reconstruct the complete three-dimensional geometry of objects analyzed, the goal of stereology is not exact reconstruction but obtainment of objective, quantitative, and possibly simple description of the structure tested, suitable for classification and comparison with other structures. It is noteworthy that in medicine tomography and stereology are often used together (Hilliard and Lawson 2003).

Inspection of any three-dimensional structure leads to different datasets which are limited to three categories, namely projections, sections, and 3D reconstructions (compare Fig. 1):

- Projection is the most commonly available kind of visual information. Photos taken by cameras or smartphones are in fact projections. Our sense of sight provides some 3D information after analysis of two slightly different projections. Transparency of objects or X-ray inspection allow for some insight into the internal arrangement of the investigated structures but it also provides projections.

- Section can be either physical or virtual as a subset of information from tomographic image. Single section usually does not deliver any information of 3D character.
- Three-dimensional (3D) reconstruction ensures the most complete information about the 3D structure but requires special apparatus and has numerous limitations connected with resolution and relatively high cost of analysis. Moreover, X-ray tomography cannot differentiate objects with similar atomic mass.

Main limitations of stereological methods are clearly visible in Fig. 1. Stereology does not allow to characterize spatial connectivity or three-dimensional shape and orientation of objects under consideration. This kind of information can be effectively obtained using tomographic inspection. Consequently, it makes an impression that stereology is no longer necessary. On the other hand, tomography is very effective in detection of pores but simultaneously useless in detection of the boundaries in polycrystalline, single-phase materials. Sections and projections can be obtained using numerous methods: photographic documentation, light microscopy, including polarization or DIC (differential interference contrast), transmission (TEM), and scanning (SEM) electron microscopy, EBSD (electron backscatter diffraction), FIB-SEM (focused ion beam), radiography, ultrasonography, AFM (atomic force microscopy), radar and sonar, etc. Multitude of these techniques assures the necessity of stereological analysis.

Stereology is based on statistical analysis of the spatial properties of objects and returns statistically exact estimators of various parameters. However, derivation of the basic relations requires some assumptions concerning properties of the examined structure. The most important statement tells that the arrangement of objects should be IUR, it means independent, uniform, and random. This assumption assures that all the sections are statistically identical and enables derivation of numerous equations. Unfortunately, in many cases the investigated structure is not IUR (compare Fig. 2b–d).

Stereology, Fig. 2 Models of different arrangements of objects: (a) IUR objects, (b) linearly oriented objects, (c) periodic arrangement of objects, (d) clustered objects, (e) different size, (f) different shape. Details in the text (Source: Wojnar L (2020))

Stereology, Fig. 3 Basic notions used in stereological analysis (Source: Wojnar L (2020))

Possible solutions to such problems are presented later in this chapter.

This is postulated that for full stereological description of a group of objects it is necessary and sufficient to quantify four characteristics:

- **Amount:** This is the most popular and relatively simple for evaluation parameter. The amount of objects is quantified by their total volume in 3D space or by the total surface area of sections in 2D images. Number of objects is not a measure of amount. All the images in Fig. 2 have the same amount of black objects.
- **Size:** The most natural measure of an individual object size is its volume, but this measure is usually impossible for precise evaluation except of tomographic images. There are different, relatively easy for evaluation, measures of size. However, usually there is not exact relation between different size characteristics. Size of objects in Fig. 4 is the same in all the images. Greater objects can be found only in Fig. 4e.
- **Shape:** This parameter is very important but simultaneously very difficult for quantification due to the fact that even from a small piece of plasticine an infinite number of different shapes can be created. Consequently, any parameter unambiguously describing shape would have an

Stereology, Fig. 4 Manual analysis in stereology: (a) random test points, (b) networked test points as knots of the network, (c) linear method, (d) curvilinear test lines (Source: Wojnar L (2020))

unlimited value and this is obviously impossible. To partially solve this problem, the so-called shape factors are used. In Fig. 4a–e all the images contain objects of the same shape. Only objects in Fig. 4f have different shape.

- Arrangement (in the sense of location): This factor can have decisive impact on properties of various materials, like, for example, rocks or soils. Simultaneously, quantification of arrangement is the most difficult task. Object distribution is approximately uniform and random only in Figs. 4a, e, and f. In Figs. 4b, c, and d objects are oriented, periodically placed or clustered, respectively. This is also noteworthy that every structure, if only observed at sufficiently large magnification, becomes inhomogeneous. Therefore, quantification of arrangement has no universal measures.

Basic Principles and Methods

Basic notions used in the further part of this chapter are presented in Fig. 3. Stereological analysis is limited to a volume of space, called test volume. It contains objects, which can be three-dimensional, flat, or linear. They are examined using section planes, test lines (intercepts), and

test points. Test lines cut the surfaces of objects or edges of object sections at locations called intersection points. Line segments lying within an object, with the length limited by intersection points, are called chords.

Symbols used in stereological analysis are internationally recognized and used (Table 1). If the symbol is denoted by a capital letter, it refers to the whole test space or the whole set of tested objects. Lowercase letters denote either single object or mean values for a set of objects. In some cases, for example, in medicine, different notion for the same quantities can be found.

The most commonly used 12 stereological parameters are called global as they describe the whole sets of objects, not individual ones. These parameters have the symbol X_Y , where X denotes the measured quantity (for example, surface area) and the subscript index Y denotes reference space (for example, test volume). In turn mean values characterizing single objects are called local parameters (Table 2).

Local parameters, being simply mean values of various parameters, are easier for understanding and interpretation. Unfortunately, it can be completely misleading. For example, in the case of two, approximately equinumerous sets of large and small objects the mean value can describe a nonexistent object. It can lead to erroneous conclusions. In such a case a

Stereology, Table 1 Basic symbols and quantities used in stereology

Symbol	SI unit	Explanations and comments
A, a	m^2	Area; surface area of a flat surface (object, section, test area, etc.)
B, b	m	Border; length of an object outline, perimeter, or sum of such outlines
D, d	m	Diameter; diameter of a circle, sphere, object, etc. Sometimes the so-called equivalent diameter is traditionally used for characterization of irregular figures (usually sections). It is equal to the diameter of a circle with surface area equal to the surface area of the analyzed object
L, l	m	Length; length of test lines, chords, projections, etc. Also used for curved lines, like borders, perimeters, central lines of elongated objects, etc.
N, n	–	Number; number of objects, chords, etc.
P, p	–	Point; number of test or intersection points, knots of test grids, etc.
S, s	m^2	Surface; surface area of a curvilinear surface of an object or set of objects
V, v	m^3	Volume; volume of an object, set of objects, or test volume

Stereology, Table 2 Selected parameters used in stereology

Symbol	SI unit	Explanations and comments
Global parameters referred to a three-dimensional space		
V_V	–	Volume fraction; ratio of the total volume of tested objects to the total volume of tests space
S_V	m^{-1}	Specific surface area; ratio of the total surface area of tested objects to the total volume of test space
L_V	m^{-2}	Specific length; ratio of the total length of tested lineal objects to the total volume of test space
N_V	m^{-3}	Number of objects per unit test volume
Global parameters referred to a two-dimensional space		
A_A	–	Area fraction; ratio of the sum of section areas to the total area of the test plane
L_A	m^{-1}	Length per unit test area; ratio of the total length of examined linear objects to the area of test surface containing these objects
N_A	m^{-2}	Number of objects per unit test area; ratio of the total number of examined objects to the area of test surface containing these objects
P_A	m^{-2}	Number of points per unit test area; ratio of the total number of intersection or test points to the area of test surface containing these points
Global parameters referred to a one-dimensional space		
L_L	–	Linear fraction; ratio of the sum of chords of tested objects to the total length of test lines
N_L	m^{-1}	Number of objects per unit test line length
P_L	m^{-1}	Number of points per unit test line length
Global parameters referred to a zero-dimensional space		
P_P	–	Point fraction; ratio of the number of points hitting the tested objects and total number of test points
Local parameters		
$\bar{v}$	m^3	Mean object volume
$\bar{a}$	m^2	Mean surface area of a flat object or section
$\bar{s}$	m^2	Mean object surface area in 3D
$\bar{l}$	m	Mean chord or projection length
$\bar{d}$	m	Mean object diameter
$\bar{\lambda}$	m	Mean free path; mean distance between objects measured along a single direction
$\bar{h}$	m	Mean object height or spacing

safe solution is the use of statistical distributions of measured values.

Global and local parameters are closely related (see Eqs. (1)–(5), Table 3). Some of the relations presented in Table 3 are older than stereology but only development of this new branch of science allowed for their orderly organization, classification, and theoretical foundations. Surprisingly, in spite of the passage of time, the 55-years-old monograph by Underwood is still often cited as a source of

information on classical stereological methods (Underwood 1970).

The roots of stereology are firmly connected with the idea of three-dimensional interpretation of two-dimensional cross sections. Surprisingly, only four relations from Table 3 devoted to evaluation of V_V , S_V , L_V , and N_V give parameters which are strictly related to three-dimensional structures. It explains the need for upgrading the definition of stereology, presented in the introductory section.

Stereology, Table 3 Selected equations used in stereology

Equation number	Equation	Explanations and comments
(1)	$\bar{v} = \frac{V_V}{N_V}$	Exact relation of limited applicability due to problems with evaluation of N_V
(2)	$\bar{s} = \frac{S_V}{N_V}$	Easy tool for estimation of the mean surface area of an object of any shape. The use of Eq. (7) is necessary. Limited applicability due to problems with evaluation of N_V
(3)	$\bar{a} = \frac{A_A}{N_A}$	Simple relation, very convenient in the case of single-phase materials where $L_L = 1$
(4)	$\bar{l} = \frac{L_L}{N_L}$	Simple relation, very convenient in the case of single-phase materials where $L_L = 1$
(5)	$\lambda = \frac{1-L_L}{N_L}$	Characterizes object spacing in a single direction, parallel to the test line(s). Allows for measurements in different directions, and so is suitable for analysis of oriented structures
(6)	$V_V = A_A = L_L = P_P$	The simplest possible, very elegant, and very useful stereological equation. Probably the most popular stereological relation. It is restricted to IUR structures only
(7)	$S_V = 2P_L$	One of the most important relations in stereology. Unbiased estimation of the surface area of curvilinear objects in the space. Not applicable for oriented sets of surfaces
(8)	$L_V = 2P_A$	Unbiased estimation of the length of curvilinear objects in the space. Not applicable for oriented sets of lines
(9)	$N_V = \frac{N_A}{\bar{h}}$	Relation difficult for practical application due to problems with evaluation of the $\bar{h}$ value. $\bar{h}$ denotes mean height of an object, i.e., its projected length in direction perpendicular to the test plane
(10)	$L_A = \frac{\pi}{2}P_L$	Unbiased estimation of the length of curvilinear objects in the plane. Not applicable for oriented sets of lines
(11)	$N_L = \frac{P_L}{2}$	Practically obvious and straightforward relation which allows unbiased automatic evaluation of the number of objects cut by a section line
(12)	$N_A = \frac{1}{A}(n_i + 0.5n_e + 0.25n_c)$	Known as Jeffries' method for a rectangle. Used for unbiased estimation of the number of objects. Symbols denote: n_i – number of internal objects, n_e – number of objects cut by the image edge, n_c – number of objects at the corners of the image. Gives small, negligible errors in the case of objects placed outside corners but simultaneously cut by two edges of the image

Figure 4 illustrates classical, manual methods of analysis. One of the main achievements in stereology is the possibility to evaluate complex quantities, like volume, by simple measurements or even counts. An excellent example of the beauty and cleverness of stereological methods is Eq. (6) where volume fraction can be estimated on the basis of simple counts. Test points are placed randomly over the analyzed image (Fig. 4a) and volume fraction is estimated as a ratio of the number of points hitting the analyzed objects to the total number of points.

The use of randomly distributed points is correct, but in practice inconvenient. Much attention has to be paid to control which points have already been analyzed. Much faster and more convenient is application of a network of lines, where test points are simply nodes of the network (Fig. 4b). If the objects are IUR, application of the networked points preserves randomness of the whole analysis. During manual analysis some points seem to be placed just on the boundary between objects and the matrix. In such a doubtful case the point should be counted as $\frac{1}{2}$ instead of 1. This simple rule allows to avoid systematic errors.

In the case of repeated measurements performed on the same image the test grid can be applied at various locations and rotated by different angles. Consequently, some scatter of results will be observed. The relative error γ of V_V estimation using point method can be expressed as:

$$\gamma = u_\alpha \sqrt{\frac{1 - V_V}{P_T \cdot V_V}} \quad (13)$$

where:

α – significance level, usually 0.05,

U – statistics of the normal distribution; for $\alpha = 0.05$

$$U_\alpha = 1.96 \cong 2$$

P_T – number of test points

So, if $V_V = 0.1$, then 3600 points have to be tested in order to ensure 10% relative error. It should be stressed that Eq. (13) returns relative error of the method only, without any relation to improper sampling, nonhomogeneity of the material tested, etc. The number of points necessary to be tested is really very high. Therefore automated methods, usually using computerized image analysis, are used whenever possible. In principle the method is the same in manual and automated measurements. The main difference depends on the fact that automated methods use all the points (pixels) in the image and therefore relative error of the method reaches the value of zero. In spite of it errors in automatic analysis can be even larger than in the case of manual methods. The main source of problems is improper segmentation. Due to the digital character of images even a relatively small change in threshold values can introduce (in the case of small objects) more than 100% difference in the results.

Linear methods (compare Fig. 4c) are less popular in estimation of volume fraction. Counting is not sufficient in this case and one has to measure the lengths of chords, seen as white line segments in Fig. 4c. Such measurements can take more time and introduce more errors than simple point counting. This is a consequence of errors in length measurements. On the other hand, linear analysis is a perfect tool for estimation of the specific surface area (Eq. (7)). It is noteworthy that P_L estimation can be executed with the help of test lines of any shape, for example, circular (Fig. 4d). Irregular shapes of test lines are not used because it is difficult to fix their lengths. Relative error of the method of volume fraction evaluation using linear analysis can be expressed as:

$$\gamma = U_\alpha \sqrt{\frac{2(1 - V_V)^2}{N_T}} \quad (14)$$

where

N_T – number of chords taken for analysis

Although shape of objects building the internal structure of solid bodies is one of the most important factors affecting their properties, it is difficult to find a satisfactory definition. Possibly the best one can be found in Wikipedia Web page: the shape of a set of points is all the geometrical information that is invariant to translations, rotations, and size changes (Shape 2020).

Due to the reasons presented earlier, it is impossible to characterize any shape unambiguously by single numbers. The problem is partially successfully solved by introduction of the so-called shape coefficients. They are dimensionless numbers, thus invariant with size changes, describing how similar a given shape is to the ideal, model shape. Consequently, any shape factor has only a limited applicability, related to the reference object. In most cases circle is chosen as a reference shape for objects observed in 2D planes. There exists no universally accepted symbol for shape factor and here the letter q is chosen.

The simplest shape factor $q1$ is suitable for characterization of the elongation of ellipsoidal objects. It is a ratio of the

longest projection length a and projection length b measured in direction perpendicular to the longest projection (Fig. 5a):

$$q1 = \frac{a}{b} \quad (15)$$

This shape factor reaches the value $q1 = 1$ for a circle and corresponds well with rough judgement done without measurements by a human observer. However, it can reach very high values for significantly elongated objects. Therefore a modified elongation parameter $q2$ is used, for example, in image analysis software:

$$q2 = \frac{a - b}{a + b} \quad (16)$$

where $q2$ is equal to 0 for a perfect circle and goes asymptotically to 1 for very long and thin objects. Parameters $q1$ and $q2$ are not sensitive to differences in shapes without any elongation (Fig. 5b). For such shapes the next shape factor, called circularity, can be defined:

$$q3 = 4\pi \frac{A}{L^2} \quad (17)$$

The use of the second power of the perimeter assures constant value for objects of the same shape but different sizes. Circularity reaches the value of 1 for a perfect circle and lower values for other shapes. Extremely irregular borders can lead to circularity values close to zero. This parameter is suitable for characterization of the shapes of islands or lakes.

One can meet also objects with shapes being a combination of elongation and irregularity of the border line. For characterization of such objects one can use the next shape factor, $q4$, which is a ratio of the circumscribed circle diameter d_2 to the inscribed circle diameter d_1 (Fig. 5c):

$$q4 = \frac{d_2}{d_1} \quad (18)$$

In practice a countless number of shape factors can be invented. However, the examples presented above are among the most popular.

Stereology, Fig. 5 Parameters for evaluation of shape factors (Source: Wojnar L (2020))

Sampling Strategy and Testing Objects of Any Shape or Arrangement

Stereology established sampling strategies which can be successfully applied in any research, including even the most modern tools connected with tomography and computerized image analysis. Sections (or images) for analysis can be taken in any way under assumption that the structure is IUR and the section covers enough large area. Definition how large this area should be is usually problematic. Therefore, sections taken either in a fully random way or systematic sampling design prior to experiments should be applied. Images taken by human observers without the above-mentioned restrictions often introduce significant bias to the analysis. This is a consequence of the fact that human observers intuitively choose places which look interesting, contain large objects, offers good quality, etc. Moreover, in linear analysis the test lines should be placed away in a distance which assures avoidance of multiple hitting the same object.

During image acquisition the fundamental problem is their resolution. It should be good enough for clear recognition of the smallest objects analyzed. These objects should contain several dozen pixels in order to be correctly classified. In the case of microscopic examination, the proper choice of magnification and, consequently, resolution is of the highest importance. Higher magnification allows for observation of smaller objects. Unfortunately, the images become less homogeneous and we lose information of large-scale arrangement of objects or even whole largest objects. Proper choice of microscopic magnification is always a compromise between details and global information.

One of the most common questions is: How many objects or images should be analyzed? There is no single rule for a proper choice of necessary number of observations. It is recommended to control the scatter of results. If the standard deviation of the results of measurements remains stable in spite of enlargement of the number of measurements, this number is sufficient.

Another very big problem is caused by structures which are not IUR. Independent, uniform, and random arrangement of objects can be found in ingenious rocks, like granite. In contrast, sedimentary rocks or various types of soil usually exhibit layered structure. Even more complicated structure of rocks, with curvilinear layers, is observed in the regions of massive rock formation movements. To make quantification even more complicated, tectonic faults can be taken under consideration.

Sometimes finding appropriate solution is quite easy. In order to evaluate the total border length of elongated and oriented objects (like in Fig. 2b) it is sufficient to apply circular test lines (Fig. 4d) and Eq. (10) can be applied.

Another example of simple tricks which allow to avoid systematic errors is quantification of the volume fraction of

objects in layered structures (Fig. 6). If one chooses sections parallel to the layers (traces of cutting marked in blue), a saw-tooth wave will illustrate changes in estimated volume fraction as a function of section location (blue line in Fig. 6). It is sufficient to choose sections perpendicular to the layers (exemplary traces of such section are marked in red in Fig. 6) in order to get correct overall volume fraction of dark objects. Approximately, the same results will be obtained at any location of the section plane. Variation in the results will depend in this last case only on the section area and inhomogeneity of the structure examined. Sections perpendicular to the layers can be used also for estimation of the saw-tooth relation obtained from sections parallel to the layers. For estimation of this relation it is sufficient to evaluate volume fraction with the help of linear method with test lines parallel to the traces of layers. Another possible solution is to apply a set of equally distant points placed along a line parallel to the traces of layers and point counting method.

Specific surface area S_V is a very important stereological parameter. It can affect various properties and is one of the measures of size, because it increases when objects tend to divide into smaller segments. The method for estimating S_V on the basis of simple counts and linear method (Eq. (7)) was invented in the year 1945 by S. Saltykov. Unfortunately, this method works well only in the case of IUR objects. The scientific community has been waiting 42 years for generalization of this method, which allows for analysis of structures with objects of any shape and spatial arrangement (Baddeley et al. 1987).

Lest us analyze the method of vertical sections which allows for unbiased estimation of the surface area of objects of any shape. The result of analysis will be unbiased if the test lines (secants) are IUR, i.e., uniform, independent, and random. Intuitively it can be assured if we take a number of coaxial, uniformly distributed test planes (Fig. 7a). If we need

Stereology, Fig. 6 Evaluation of volume fraction in layered structures (Source: Wojnar L (2020))

Stereology, Fig. 7 Assessment of the surface area of an object of any shape: (a) object and vertical sections, (b) random test lines in a plane, (c) spatial distribution of test lines, and (d) exemplary cycloidal test line (Source: Wojnar L (2020))

to prepare physical sectioning, the object has to be put on a horizontal plane and the sections, as well as the reference axis, should be perpendicular to this plane. Consequently, they will be vertical. It explains the name: method of vertical sections, sometimes called a method of coaxial sections. The intuitive reasoning tells: if we have uniformly distributed vertical (coaxial) sections and the test lines in every section will be IUR (Fig. 7b), the sampling should be also IUR. Unfortunately, this not a case. If all the test lines fit a single point we can analyze their spatial distribution by analyzing distribution of the intersections with the surface of a hemisphere (Fig. 7c). Now, it becomes clear that the surface density of intersection points is much higher near the pole than close to the equator.

To solve this problem one should apply more secants parallel to the basic plane in comparison with the number of secants parallel to the vertical direction. And the number of secants with middle orientation should gradually change. Baddeley, Gundersen, and Cruz-Orive (1987) have invented a tricky and simple solution: a curvilinear test line which is a cycloid (Fig. 7d). During evaluation of the number of intersection PL with cycloids one should remember that the length of a cycloid of height 1 is equal to 2. Analysis of the vertical cross sections with the help of a set of cycloids allows for the direct use of Eq. (7) and assures unbiased estimation of the specific surface area.

Other Stereological Methods

The methods presented above belongs to a group of basic, most popular and widely used. There are also many other stereological tools but they are not presented in detail due to a limited volume of this chapter or limited applicability in geosciences.

Quantitative fractography covers a set of tools devoted to analysis of fracture surfaces. It is also based on analysis of sections and projections but characterizes distribution of several objects over curvilinear surfaces instead of the whole volume. These methods adapted general-purpose stereological relations and offer new parameters as well as relations suited to specific characteristics of fracture surfaces. Quantitative fractography has been extensively developed in the 1980s of the twentieth century. An overview available in ASM Handbook (Underwood and Banerji 2013) is in fact a copy of the chapter published in 1987. Some more advanced concepts have been presented by Wojnar and Kumosa (1990). Currently quantitative fractography is almost forgotten. This is a consequence of extensive use of confocal microscopy, stereoscopic methods, and, last of all, tomography. This last method is especially useful in the case of analysis of rocks being potential gas or oil deposits. Quantitative fractography could be possibly applied in analyses of land relief, glacier melting, etc.

Stereological methods are sometimes divided into two groups, namely model-based and design-based stereology (Stereology information 2020). Model-based stereology is recognized in this classification as a set of classical methods, currently a little bit outdated. Model-based methods work well only if the models truly represent the real objects. In other words, these methods are not assumption free and their applicability is limited by these assumptions.

Typical examples of model-based procedures are the methods for evaluation of particle size distributions. Among them one can list Saltykov (area analysis), Spector (chord analysis), or Lord and Willis (graphical analysis of chords). All these methods are restricted to a model shape of sphere (Underwood 1970). All these methods have the same drawback – the total number of objects and final shape of the distribution function are computed on the basis of analysis of smallest particles in experimental distribution function. Unfortunately, measurements or counts within this class of objects are coupled with the highest bias. The results can be corrected during further analysis but it requires additional assumptions.

Design-based stereology is presented as a more universal and powerful set of methods. Its main property is a lack of assumptions concerning shape, size, orientation, and distribution. Nevertheless, this division is rather artificial and not precise. Classical stereological methods were derived with only one, but relatively strong assumption: the objects analyzed should be IUR (independent, uniform, and random). If any structure investigated does not fulfill this assumption it can be analyzed if only the test system assures independent, uniform, and random sampling and measurements. The method of vertical section is a very good example. Consequently, even the oldest stereological methods can be used within the framework of design-based stereology.

One of the most difficult tasks is evaluation of the number of objects in the tested volume (N_V). This parameter can be easily estimated using CT methods. Stereological analysis requires assumptions concerning shape and is usually very approximate. The problem can be solved by the use of disector, i.e., analysis of two parallel sections, called reference and lookup, respectively. The rule of counting is very simple: objects visible only in the reference section are counted as related to the test volume between sections. The main restriction of this method is the distance between test sections. It has to be smaller than the possible smallest object size. Consequently, this method is successful in analysis of cells or cell nuclei. Unfortunately, it is practically useless in inspection of minerals, rocks, or soils where very small objects are often observed.

The next example of design-based stereology is surfactor, a method for estimation of the surface area. This method

requires isotropic sectioning. It is also applicable mainly for biological structures and in the case of rocks or soils, the use of classical or vertical sections method will be a better choice.

Another subset of stereological methods is known under the name of second-order stereology (Stereology information 2020). These techniques are devoted to relationships, for example, the distribution of particles. One should remember that these methods have been initially designed for biological research and possible applications of second-order stereology methods in geosciences is limited. Therefore, and also due to the limited space, second-order stereology is not discussed in this chapter.

Stereology in Computer Era

The unprecedented progress in computer technology enabled invention or significant improvement in numerous research methods suitable for three-dimensional analysis of various structures. Below there are listed some examples:

- CT (computed tomography) offers three-dimensional (3D) reconstruction and solves the problem of evaluation of spatial arrangement and connectivity, which cannot be characterized using stereological methods
- EBSD (electron backscatter diffraction) used in scanning electron microscopy (SEM) allows for precise evaluation of shape and orientation of single grains in polycrystalline materials
- FIB-SEM (focused ion beam) enables 3D reconstruction of micro volumes
- Confocal microscopy, which allows for quick analysis of curved surfaces without overlaps or 3D analysis of transparent tissues (in microscale) or
- Seismic tomography (suitable for a very-large-scale research)

Consequently, the knowledge of stereology is often neglected.

Simultaneously, 2D imaging still is and probably will be in the near future very popular in any research. Such situation is clearly visible in medicine. In spite of the progress in CT, MRI (magnetic resonance imaging) or PET (positron emission tomography) techniques, simple X-ray, or USG images are commonly used in renowned hospitals and the quality of these 2D techniques is gradually improved. Outside medicine an enormous flood of images comes from countless number of several cameras. Almost all these images are processed by computers and part of them is next analyzed. This analysis is performed usually with the use of computerized tools, mainly image analysis (IA) and artificial intelligence (AI).

Classical stereological analysis with manual counting or measurements is extremely laborious and time consuming, while IA and AI are very convenient as they are fast and give repeatable results. Consequently, these new methods are recognized much more attractive than stereology. There is, however, a significant risk of large errors introduced by image analysis tools. Small errors in object detection can significantly affect the results obtained and the measurement errors can be larger than in the case of manual stereological analysis. Moreover, even exact and precise results from a single image not necessarily reflect the scatter of the whole structure. And stereological tools can help to establish appropriate sampling strategy or image resolution. Further interpretation of raw data obtained from automatic measurements also is a domain of stereology. Some algorithms used in quantification in image analysis has a stereological background, for example, the Crofton formula for perimeter evaluation and techniques for unbiased evaluation of several parameters. Manual methods can be irreplaceable in the case of structures not suitable for automatic detection. Many IA software packages offer stereological plug-ins, which combine manual detection with automated measurements or calculations.

So, after decades of parallel and even concurrent development, one observes in recent years some synergy. Adding the term image analysis to the name of the International Society for Stereology has a symbolic significance. Computer technology can enormously increase effectiveness of stereological analysis and stereology can help to avoid rough errors connected with uncritical application of easy-to-use computerized tools.

Applications in Geosciences

An overview of potential development, problems, and limitations in application of stereology in geosciences has been presented many years ago by Bodziony (1993). Surprisingly, the majority of his conclusions is still valid. He stressed the role of stereological analysis in mineral liberation and quantitative evaluation of the structure of rocks and soils. Finally, Bodziony has predicted the dominating role of automatic image analysis and the need to develop image acquisition methods which ensure good contrast in the case of transparent minerals. Due to the development of new tools and progress in traditional ones one can currently analyze directly 3D data or evaluate much more complex objects than porosity only in the soil structure.

Jutzeler et al. (2012) concentrated on grain size evaluation in pyroclastic deposits created during volcanic eruptions. They use stereological analysis as an alternative to

sieving and 3D imaging. Their method of analysis, called functional stereology, is based on simulation of 2D size distribution on the basis of real or model 3D size distribution. Next, experimental data is compared to the simulated 2D distribution which allows for matching appropriate 3D size distribution. This method was validated on synthetic rock with precisely defined grain size distribution. Application of stereological analysis allows inexpensive interpretation of data obtained from image analysis and results more accurate than sieving.

An interesting concept to combine stereological methods and modern data acquisition from terrestrial lidar was presented for forest inventories (Lynch et al. 2018). Estimators of the single tree bole as well as volume and height characteristics are based on stereological principles and appropriate sampling. Forestry has not been a part of geosciences, but forests are an extremely important part of biosphere and can have some impact on classical geosciences.

In recent years stereological methods are rarely used as a main tool in data interpretation. Nevertheless, the knowledge of basic principles of stereology can play important role in correct design of the experiments, sampling, and data interpretation.

Conclusions

Classical stereological methods have been initially developed for manual analysis. In spite of this the rules and methods of stereology are suitable also for contemporary modern computerized methods of image analysis.

Possible applications of stereological methods in geosciences cover several areas, for example:

- Classical stereological analysis, i.e., evaluation of 3D parameters from 2D (two-dimensional) images
- Analysis of 2D images. Stereological methods can be helpful in unbiased estimation of the number of objects, size distributions, or shape factors
- Analysis of curvilinear surfaces, for example, fractures or topography of the Earth. Appropriate tools constitute quantitative fractography
- Evaluation of quantitative parameters of 3D objects detected using tomography or systematic sectioning
- Design of experiments, including orientation of possible sections or determination of the necessary number of objects to be analyzed, etc.

The use of stereological methods in analysis of digital images can significantly improve the results or help to

avoid erroneous quantification and therefore should be commonly applied.

Stochastic Geometry in the Geosciences

Dietrich Stoyan

Institut für Stochastik, TU Bergakademie Freiberg, Freiberg, Germany

Definition

Stochastic geometry is the branch of applied probability that studies random systems of geometrical objects scattered in 3D or 2D space. The theory considers various stochastic models, which may be cell- or pixel-based as well as object-based, and tries to determine the characteristics of these models. Modern geostatistics use successfully such model classes of stochastic geometry as marked point processes or Boolean models, and general ideas of stochastic geometry play a role in modeling and simulating geological structures. The corresponding statistical aspects (data analysis, model fitting) are treated by methods of spatial statistics and multiple-point statistics.

Overview

In geoscientific applications the geometrical objects may be of four types:

- Points as considered in the *article* ► [“Point Pattern Statistics”](#)
- Line segments, curves (1D objects), e.g., river courses/networks, centerlines of channels in fluvial reservoirs, fractures/faults seen on the Earth’s surface or in outcrops, lineaments, striations. . .
- Surface or plane pieces (2D objects), e.g., fractures, faults, joints, veins, geological horizons and boundaries, intrusion-host contacts. . .
- Bodies (3D objects), e.g., tessellation cells, specific geological bodies, grains in sedimentary, magmatic and metamorphic rocks, lobes, shales, fluvial channels. . .

These objects may range from microscopic to plate-tectonic scale.

The corresponding mathematical terms are:

- Fiber processes
- Surface processes
- Full-dimensional random sets
- Tessellations

The use of the term “process” is a mathematical convention; some readers may prefer instead the term “field”. The

objects are sets (in mathematical sense) in a 2D or 3D reference frame, usually a geographic coordinate system.

The standard reference to applied stochastic geometry in general is Chiu et al. (2013). All formulas given without reference in this text can be found in this book. Stochastic geometry has operated from the very beginning in the spirit of multiple-point statistics. It was never limited to second-order or two-point methods.

A basic difficulty of application of stochastic geometry in the geosciences consists in the fact that many of its models assume that the structures considered are stationary. That means that they (theoretically) are thought to be extendable infinitely into space and that their random fluctuations are similar everywhere in space. While this assumption is often realistic at the microscopic scale, it is often not in studies of larger geoscientific objects. Therefore, when the standard models of stochastic geometry are used, care is necessary. If, as in many situations, short-range relationships are of main interest, a clever choice of the window of observation may help; see the discussion in the article ► “Point Pattern Statistics”.

Furthermore, it is a problem that stochastic geometry has been developed as a mathematical discipline with main applications in image analysis and materials science, independently of ideas of geosciences. This has led to different terminologies. The present text follows mainly the rules of geomathematics, with some notes on the mathematical terminology.

The following presents some fundamental models of the four model classes. These models aim to help in understanding the geological/mineralogical processes of forming the observed structures and to get information about the interaction of their components, but are also the basis for characterization and simulations.

Models of Stochastic Geometry

Marked Point Processes

Marked point processes (MPP) serve as a basis for many models of stochastic geometry in the geosciences, as they describe random collectives of objects scattered in space. Formally, an MPP is a double sequence $\{[x_n, M_n]\}$ of points x_n and marks M_n . The x_n describe the locations of the objects, being constructed by the statistician (e.g., centers), while the M_n are the objects, mathematically “sets”. In the mathematical literature such an MPP is called a “germ-grain process”, germ = point and grain = mark; the set-theoretic union of all grains at their germs is called “germ-grain model”. In the geostatistical literature the term “object model” is used. Pyrcz and Deutsch (2014), section 4.4, is an excellent introduction to the statistical problems related to MPP in the geosciences.

Stationarity of MPP means invariance of the distribution under translations, which shift the points but retain the marks, i.e., $[x, M] \rightarrow [x + \delta, M]$.

The intensity λ of a stationary MPP is the mean number of points per area or volume unit. The marks are characterized by a *mark distribution*, which is a distribution of a random set, or, if the objects are parameterized, of a number or vector. Whenever possible, one tries to parameterize the marks. Simple models are balls, discs, or segments, and there are models for other objects such as channels.

Usually, there are spatial correlations between the germs and grains. A typical case is that in regions of high point density the grains tend to be small. So it is often necessary to model and simulate the point pattern $\{x_n\}$ and the marks M_n simultaneously, which makes simulations rather complicated in practice.

The Poisson Point Process

The Poisson point process is an important building stone of many models of stochastic geometry. Details are explained in the article ► “Point Pattern Statistics”. For the understanding here it may be sufficient to know that this point process is stationary and isotropic and completely spatially random (CSR), there is full independence and randomness of the point distribution. Its distribution is fully determined by the intensity λ : the random number $N(A)$ of points in a set A has a Poisson distribution with mean $\lambda v(A)$, where $v(A)$ is the area or volume of A .

The Poisson-Boolean Model

The Poisson-Boolean model, abbreviated here as PB model, is a universal and key model of stochastic geometry, which can be applied for modeling fiber processes, surface processes as well as structures of 3D bodies. It is a special object or germ-grain model, for two categories or phases. In the mathematical literature, the Poisson-Boolean model is called simply “Boolean model”, while in the geomathematical literature every model composed by grains or objects is called “Boolean”. The name was coined within the school of Georges Matheron in the context of indicator functions and random sets and refers to the English mathematician George Boole, who is for mathematicians closely related to “either-or” or “0–1-structures” (see the relationship between random set X and random field $\{Z(x)\}$ below).

The model construction is very simple. It starts with a homogeneous Poisson point process $\{x_n\}$ of intensity λ , the set of “germs”. Each germ is the center of an object or “grain”, a bounded set, which can be random. All the grains have the same distribution and are stochastically independent, which makes analysis and simulation easy. The set-theoretic union X of all the grains $M_n + x_n$ is called the Poisson-Boolean model.

Stochastic Geometry in the Geosciences, Fig. 1 A simulated PB model. In a cube and in its neighborhood random points are scattered. Each point is the center of a ball of random radius. The set-theoretic union of all balls and ball-pieces in the cube is a sample of a PB model. (Data courtesy of Felix Ballani)

A simple example is the case where the grains are balls with random radii. Figure 1 shows a piece of a simulated sample of a PB model with spherical grains.

The term “germ” suggests a relationship to some growth model. Indeed, the germs may be starting points of growth and with increasing time the grains may grow. The corresponding formula for the time-dependent volume fraction $V_V(t)$ of the space occupied by the grains is named the *Johnson–Mehl–Avrami–Kolmogorov crystal-growth formula*.

For the PB model there exists an elaborate mathematical theory (Chiu et al. 2013). It is stationary and, if the grain distribution is rotation-invariant, isotropic. For many distributional summary characteristics, formulas are available in the case of convex grains. Some examples are given here for the three-dimensional case:

- Volume fraction V_V = part of space covered by the grains:

$$V_V = 1 - \exp(-\lambda \bar{V}), \quad (1)$$

where $\bar{V}$ is the mean grain volume.

- Covariance $C(r)$ = probability that two points of inter-point distance r both lie within the grains of the model, in the isotropic case:

$$C(r) = 1 - \exp(-\lambda \bar{\gamma}(r)) \text{ for } r \geq 0, \quad (2)$$

where $\bar{\gamma}(r)$ is the so-called set-covariance of the grains, a statistical grain characteristic for which formulas exist.

- Spherical contact distribution function $H_s(r)$ = distribution function of the distance from a random test point outside the grains to the boundary of the PB model, in the case of spherical grains:

$$H_s(r) = 1 - \exp\left(-\frac{4}{3}\lambda r\left(3\bar{R}^2 + 3r\bar{R} + r^2\right)\right) \text{ for } r \geq 0, \quad (3)$$

where $\bar{R}$ and $\bar{R}^2$ are the first two moments of the sphere radius R .

When a line intersects a PB model, it creates a series of intervals, called chords, which are alternating within and outside of the set X . Their random lengths are independent, with distribution depending on the grain distribution for “in” and exponential distribution for “out”. The intersection of a PB model with a plane/line is a 2D/1D PB model.

In small-scale applications, e.g., of porous media, the PB model is used often for producing more or less realistic geometrical patterns, and the grain shapes and the Poisson process intensity are chosen only from the standpoint of the final result, the statistical properties of the resulting random-set pattern. Typical three-dimensional grains are balls and the so-called Poisson-polyhedra, i.e., polyhedra generated by the Poisson plane process. In this sense the porous structure of sandstones was modeled (Arns et al. 2002); of course, a PB model cannot mimic sandstone formation.

Statistical methods, including goodness-of-fit tests, for the PB model are presented in Chiu et al. (2013). Statistics is difficult, if only the union set X is given as in Fig. 1 and not the germs and grains. Figure 2 shows the Assakao sandstone data set as in Haldorsen and Chang (1986). It looks like a PB model with grains = shale streaks (considered as horizontal segments of random lengths); as germs the segment centers may be used. However, the germs show local alignments (Haldorsen and Chang 1986) and the streak lengths are spatially correlated, in regions of high streak density the lengths tend to be short, so the hypothesis that this structure belongs to a PB model must be rejected, without a formal test.

Fiber Processes

Fiber processes are mathematical models for random systems of curve pieces in 2D or 3D, if in 2D, also called “networks.” There exists some theory for such systems in the case of stationarity (Chiu et al. 2013). The corresponding mean-value parameter is L_A (in 2D) or L_V (in 3D), the mean length of fiber pieces per unit area or volume. The orientations of the fibers are described by a rose of directions. In the stationary

Stochastic Geometry in the Geosciences, Fig. 2

The Assakao Sandstone data set. The data are from Haldorsen and Chang (1986). The formation is generally sandstone (white) with occasional shale streaks (black). This cannot be seen as a sample of a *Poisson* Boolean model, since the streaks tend to form clusters if being of short length. The pattern can also be interpreted as a line-segment process

and isotropic case the spatial length density L_V can be determined by stereology. Spatial correlations in a fiber process can be described by suitable second-order characteristics (Chiu et al. 2013).

On a large scale, fiber systems appear in the planar case as fracture networks at the surface of Earth or at rock outcrops. In some cases it is important to give the fibers a random thickness.

A simple model of a fiber process (both in 2D and 3D) is the *PB segment process*. This is a PB model where the grains are line segments of random length and orientation, while the germs stand for nuclei. The corresponding PB model is a system of segments, randomly distributed in the plane or in the space. It satisfies $L_V = \lambda \cdot \bar{l}$, where $\bar{l}$ is the mean segment length. The spherical contact distribution function in 3D is

$$H_s(r) = 1 - \exp\left(-\lambda\pi r^2\left(\bar{l} + \frac{4r}{3}\right)\right) \text{ for } r \geq 0.$$

This model serves as a starting point for the construction of more realistic models, by making the fibers sinuous, thick, and interacting. There are models of fracture networks with nucleation, growth, and arresting (Chiu et al. 2013; Davy et al. 2013), where differential equations or the Weibull fracture model of materials engineering introduce the temporal element, which lead to power laws.

Surface Processes

Surface processes are mathematical models for systems of 2D sheets in 3D space. Typical cases are joint systems or systems of boundaries between distinct geological facies or discrete fracture networks (DFN). Wellmann and Caumon (2018) is an excellent review on geological subsurface detection and modeling.

There exists some mathematical theory for such systems in the case of stationarity (Chiu et al. 2013). The corresponding mean-value parameter is S_V , the mean (surface) area per unit volume. The directionality of the surfaces is described by a rose of orientations of surface normals. In the stationary and isotropic case S_V can be determined by Eq. (9). Spatial correlations in a surface process can be described by suitable second-order characteristics (Chiu et al. 2013).

A simple model of a surface process is the *PB disc process*. This is a PB model where the grains are discs of random size and orientation randomly scattered in the space; the germs may stand for faults. It implies $S_V = \lambda \cdot \bar{S}$; where $\bar{S}$ is the mean disc area. The spherical contact distribution function is

$$H_s(r) = 1 - \exp\left(-\lambda\pi r\left(2\bar{R}^2 + \pi r\bar{R} + \frac{4r^2}{3}\right)\right) \text{ for } r \geq 0,$$

where $\bar{R}$ and $\bar{R}^2$ are the first two moments of disc radius. The parameter of the exponential distribution of chord lengths on lines intersecting the disc system is $\lambda\pi\bar{R}^2/2$. This simple model was used for modeling DFNs; it was refined, for example, in (Bonneau et al. 2016) by sequential seeding further discs according to a starting PB disc process following rules that take into account the ages of discs.

A further model is the *Poisson plane process*, a random system of planes in 3D; see Fig. 3. This is not a system of germs and grains (= planes), but it is defined as a Poisson point process in a 3D representation space. This highly idealized model serves sometimes as building stone for more complicated models.

The intersection with a line yields a linear Poisson process of intensity $P_L = S_V/2$, the number of planes hitting a fixed convex set has a Poisson distribution.

The planes of a Poisson plane process generate a tessellation of the space in convex polyhedral cells, the probability

Stochastic Geometry in the Geosciences, Fig. 3 Poisson plane process. Simulated sample of a Poisson plane process. (Data courtesy of Felix Ballani)

distribution of which constitutes the so-called *Poisson polyhedron*, which is a model for crystalline grains in object models.

Modeling and Simulating DFNs

Discrete fracture networks are studied in geology for understanding tectonics and geological structures and in engineering for characterizing hydraulic and mechanical properties of rock mass in the context of studies of groundwater or hydrocarbon flow and of storage constructions. For this, plausible 3D models are indispensable.

Here three approaches for unconditional simulation of fault networks are mentioned, which are quite different but nevertheless two of them go under the same name GEOFRAC: the agglomerative approach by Koike et al. (2015) and the disruptive approach by Ivanova et al. (2014). In both approaches a single fracture or fault is a planar convex set, not a disc. Of course, the actual shape of fractures is more complicated: fault surfaces are rough surfaces that may be modeled as random fields, as also aperture or void height. Often surfaces are represented as polygonal surfaces, which can be modified by perturbing its nodes. The third, a sequential approach is described in the papers Cherpeau et al. (2010) and Cherpeau and Caumon (2015).

The Sequential Approach The algorithm sequentially simulates faults in the domain of interest. The faults are grouped into fault families according to regional tectonic knowledge and ranked chronologically. Each fault is modeled as a finite

level surface, which allows for truncation in the course of the simulation. The fault centers are randomly distributed, partly related to older and previously simulated faults; the faults are characterized by orientation, size, and sinuosity parameters (Cherpeau et al. 2010). The paper (Cherpeau and Caumon 2015) contains a flow chart that shows details of the algorithm. Important is a step which improves the initial geometry by various filtering operations. Also information from fault traces from seismic surveys or outcrops is used. Figure 4 shows some simulated fault families.

The Agglomerative Approach The model has as starting point a nonstationary PB model, the germs of which form an inhomogeneous Poisson process with intensity function piecewise constant in 3D grid cells, determined by data. The grains are discs of equal size but of spatially correlated orientation, also its distribution comes from data. These discs are connected by some rules to larger objects that are simplified geometrically by replacing them by flat figures (given by mean strike and dip) and forming the convex hull, which yields the faults.

The Disruptive Approach The model has as starting point a Poisson plane process with a specified orientation distribution and area density S_V , which is also the final area density of the fracture system. On all planes of the process, points of independent Poisson processes of the same intensity ρ are scattered and the corresponding 2D Voronoi tessellations are constructed. The polygonal cells of these tessellations are the faults of the final fracture system, after changing their locations and orientations by random translations and rotations, which make the polygons to mutually intersect.

Full-Dimensional Random Sets

General

All geometric two-phase structures considered in this entry are random sets. This section focuses on sets of full spatial dimension, i.e., sets consisting of planar components if in 2D and of spatial components such as bodies if in 3D. Additionally, it is assumed that these structures, which are denoted by X , are stationary and isotropic. They have a positive *area* (if 2D) or *volume fraction* (if 3D) A_A or V_V , respectively, for which here the general symbol p is used.

Such random sets are described by various statistical summary characteristics, which are already explained for the PB model. The simplest is p = part of space covered by X = probability that a random test point hits X . The second-order behavior is characterized by the *covariance* $C(r)$, the probability that both members of a test point pair of inter-point distance r hit X . These characteristics belong to a traditional geostatistical view of random sets, which results from the fact that each random set X can be interpreted as a random field

Stochastic Geometry in the Geosciences, Fig. 4 Three fault families. Three simulated samples of fault systems by the sequential approach (Cherpeau et al. 2010)

$\{Z(x)\}$ by using the indicator function $1_X(x) = 1$ if $x \in X$ and $= 0$ otherwise and setting $Z(x) = 1_X(x)$. The mean of this field is p and the variogram is

$$\gamma_z(r) = p - C(r) \text{ for } r \geq 0. \quad (4)$$

However, there are many further summary characteristics of random sets, which are beyond geostatistical two-point thinking, sometimes used in the context of “multiple-point statistics.” For example, the empty space between components of X is characterized by the so-called *contact distribution functions*, e.g., the *spherical* $H_s(r)$ as explained for the PB model. A similar characteristic is the *linear* contact distribution function $H_l(r)$, which is the distribution of the random distance from a test point outside of X to X , measured in random direction. This $H_l(r)$ is closely related to the *chord length distribution function*. Some of these functions also make sense for point, fiber, and surface processes. Elements of statistics for random sets are presented in Chiu et al. (2013).

Statistics for single objects or grains uses typically parameterized models developed for special cases. Examples are channels (Hauge et al. 2017; Rongier et al. 2017), lobes (Pyrz and Deutsch 2014), and faults as in DFNs.

Three Model Classes for Full-Dimensional Random Sets

1. Pixel models, i.e., sets constructed by cells or pixels of two colors, where all pixels of the same color form the random set
2. Object models or germ-grain models
3. Sets constructed from random fields

A class of *pixel models* are Markov random fields, which can be equivalently seen as Gibbs fields, which are described for

the bivariate (black-white) case in Chiu et al. (2013), they are called “Gibbs discrete random sets”. The distribution of such a set is given by

$$P(X = \xi) = \frac{1}{Z} \exp(-\beta U(\xi)), \text{ where } \xi \text{ is a black pixel set,} \quad (5)$$

where β is a positive parameter called inverse temperature, and $U(\xi)$ is the “energy” of ξ and Z a normalizing constant. Pixel sets with high energy appear rarely, and so by choosing the energy the resulting random black pixel patterns can be controlled. Generalization to the multivariate case is possible.

Object models or germ-grain models are special MPP where the marks are 3D geometrical objects, i.e., the models are collections of objects of random shape and random locations. The object centers are the germs and object bodies the grains.

A simple special case is the PB model. While here simple overlaps or intersections of the grains are possible, often in geoscientific applications the grains interact spatially, do not simply intersect, or are even definable. Therefore, object models relevant for the geosciences are rather complicated, with various mutual spatial relationships between the objects, and are usually mainly built for simulation. In these simulations, the germs play only a secondary role, which justifies the name “object model”; one cannot simulate first the germs and then add the grains. A particular case of object models are random packings of hard objects, as given by heaps of sand grains or pebbles. Also these systems are typically studied by simulation, with methods that guarantee a high volume fraction V_V (Chiu et al. 2013).

The derivation of mathematical formulas for model characteristics of germ-grain models must be seen as hopeless for recent mathematics. Only the equation for volume fraction p of a stationary germ-grain model with non-intersecting grains is simple:

$$p = \lambda \bar{V}, \quad (6)$$

where $\bar{V}$ is the mean grain volume. Sometimes the chord lengths outside the objects follow approximately exponential distributions, also for models beyond the PB model.

Statistical analyses try to estimate the intensity λ of the germ point process (with germ = center) and to determine information of the grains, perhaps mean volume, other size characteristics, and, in the best case, the mark distribution.

Excursion Sets (or level sets) are a “continuous alternative” to object models; they yield models with smooth boundaries. Such a set is constructed starting from a random field $\{Z(x)\}$ by truncating, i.e., by setting

$$X = \{x : Z(x) \geq u\}, \quad (7)$$

i.e., as the set of all points of the space where the field $\{Z(x)\}$ is larger than a threshold u . Thus, excursion sets appear in the context of indicator kriging. Often the case is considered where the random field is Gaussian and homogeneous and isotropic with mean μ , variance σ^2 , and covariance function $k(r)$ ($k(0) = \sigma^2$).

Then the area or volume fraction of X are given by $p = 1 - \Phi\left(\frac{u-\mu}{\sigma}\right)$, where $\Phi(\cdot)$ is the standard normal distribution function. For the covariance $C(r)$ there exists an integral formula, which connects it with $k(r)$.

Excursion sets can be easily simulated if $\{Z(x)\}$ is given, but their statistics, i.e., the determination of the latent random field $\{Z(x)\}$, is complicated if only samples of the random set X are available (Chiu et al. 2013). The whole theory presented above can be generalized to the case of multi-phase structures.

Representative Volume Elements

In the context of statistical analyses and physical calculations (e.g., determination of permeability or mechanical properties) a big problem is the determination of the necessary window of observation and calculation, for obtaining reliable mean values. (Windows too small yield imprecise values, windows too large cause too much work.) Using a terminology that first appeared in the context of homogenization, one speaks of representative volume elements (RVE). The determination of RVEs is sketched in (Chiu et al. 2013). It is important to note that for the same material the RVEs may differ if determined for different spatial characteristics as, for example, porosity and permeability.

Random Tessellations

General

A *tessellation* or *mosaic* is a division of the plane or of the space into cells. Such patterns occur often in the geosciences, for example, in the context of polycrystalline microstructures and crack patterns, such as columnar joint patterns in basalt or other rocks or mud cracks. There is a vast literature, use Chiu et al. (2013) as starting point, where statistical methods are also presented.

Two important models of tessellations are the Voronoi and Delaunay tessellations, which are both constructed relative to a given point pattern or process.

The Voronoi Tessellation

For the cells of a Voronoi tessellation (VT), a pattern of points called generators, nuclei, or seeds is the starting point: All points of the plane/space closer to a generator than to all other generators form its cell. These cells are convex sets, which have in the planar case the mean vertex or side number 6, if the generators form a stationary (non-lattice) point process.

A VT can be also interpreted as the result of a growth process, which explains partly its use as a model in the geosciences. The generators play the role of nuclei, in which growth begins at the same instant. The speed of growth is uniform at all nuclei and uniform in all directions, such that the nuclei become discs/balls if empty space is available. When two discs/balls come in contact, growth stops at the contact point and an edge/face begins to develop, while in other places growth is continued. Finally, the whole plane/space is divided into convex cells.

This model helps to understand and to describe natural processes, for example, the formation of sorted patterned grounds in polar or alpine environments or the process of growth of crystals in aggregates of crystals within cavities, where the growth process also goes into the third dimension, orthogonal to the plane on which the crystals grow. The cells of VTs are used as model building stones for more complicated models, as in the disruptive approach of GEOFRAC. There is software for the construction of VT both in 2D and 3D.

For the VT there exist formulas for important characteristics in the case where the generators form a homogeneous Poisson process of intensity ρ (Chiu et al. 2013): the mean of cell area is ρ^{-1} and its variance is $1.280 \rho^{-2}$. The mean number of vertex points per area unit is 2ρ , the mean cell edge density (length per unit area) is $L_A = 2\sqrt{\rho}$.

The VT is frequently used as a statistical tool, in particular for interpolation in the case of irregularly distributed points of measurement (Chiu et al. 2013). Merland et al. (2014) consider VTs in the context of constructing simulation grids, where the tessellation cells are grid cells. The generator positions are optimized so that the cell facets honor geological

structural facets. Also, VTs help in approximating the microstructure of rocks (e.g., sandstone) by two-component cell systems as starting point for modeling compression and tensile tests (Li et al. 2017), see Fig. 5.

Further Tessellation Models

Closely related to VTs are *Delaunay tessellations*, which constitute triangulations of the plane. Given a VT, the Delaunay tessellation is constructed out of the triangles/tetrahedra formed by the generators whose cells share the same vertex. Figure 6 shows a VT and some triangles of the corresponding Delaunay tessellation.

Triangulations based on Delaunay tessellations serve as statistical tools for interpolation and as means for the approximation of spatial surfaces. It makes sense to consider points of a point pattern as “neighbors” if they are connected directly by Delaunay edges.

There are many other models (Chiu et al. 2013), some of them starting from systems of edges, which may be cracks in the geoscientific context. Also tessellations on sphere

Stochastic Geometry in the Geosciences, Fig. 5 Voronoi-based tension test. Schematic result of a numerical tension test with fractures connecting neighboring pores (Li et al. 2017). *Magenta* solid phase, *yellow* pore phase, *blue* tensile cracks

surfaces appear, in particular the largest tessellation on Earth, the system of plates of the Earth’s lithosphere.

Tools of Stochastic Geometry

Regionalization

A regularized variable is a quantity $Z(x)$ defined for every location x of space. Examples are porosity at point scale at x (either 0 or 1) or ash content of coal at x (a nonnegative number, being the ash content of a small sample (ball or cube) centered at x). The statistics of regionalized variables is statistics for random fields and sometimes this goes under the name “geostatistics.” Though the basic structures of stochastic geometry are not regionalized variables, sometimes it makes sense to regionalize such structures, in order then to apply the strong methods of geostatistics. Two approaches are:

1. *Smooth geometrical structures.* For example, consider the number of points $Z(x)$ of a point process in the ball $b(x, R)$ for every point x of the space for some chosen radius R . Or, for a fiber process, consider the total length $Z(x)$ of all fiber pieces in $b(x, R)$, perhaps divided by the ball volume. For the case of statistically homogeneous and isotropic structures this approach is systematically considered in (Chiu et al. 2013), Section 6.4.4.

For inhomogeneous structures smoothing regionalization leads to estimates of the intensity function $\lambda(x)$ of a point process or spatially variable fracture density $S_V(x)$ of a fracture system. The choice of the smoothing parameter R presents a statistical problem.

2. *Generate the distance function.* Consider the distance $d(x)$ from the point x to the nearest point in the geometrical structure X . Set $Z(x) = d(x)$. If X is stationary and isotropic then so is also the random field $\{Z(x)\}$. An example for this approach is presented in Baddeley et al. (2016). There X is

a pattern of geological lineaments and the distance field is used to study correlations between X and a point pattern of copper deposits.

Simulation

Typically, all realistic structures of stochastic geometry relevant for the geosciences are too complicated for analytical-mathematical treatment. Therefore, they are studied by simulation. Simulation is used in deriving statistical summary characteristics for models, for generating samples for investigations of structural properties such as permeability, for generating test images for statistical investigations and multiple-point statistics and for generating realistic images of deposits starting from geological exploration, and for demonstrating the uncertainty of geological modeling by simulating repeatedly the same model.

Various methods are in use, depending on the type of model. There are simple direct methods, as for the PB model (see Fig. 1), for Poisson planes (see Fig. 2), or for Voronoi tessellations with respect to some point processes (using the nontrivial algorithms for the tessellation construction), see Chiu et al. (2013). For more complicated cases Markov chain Monte Carlo (MCMC) methods may be suitable for generating structures with inner interaction, e.g., for Gibbs fields.

A classical introduction to simulation is Lantuejoul (2002). For the generation of *pixel patterns* with prescribed statistical properties, geomathematics uses *multiple-point simulation*, which is of a sequential nature, see article ► “Multiple Point Statistics”. Here two examples are briefly described. In both cases, the pixels are visited on a random path through the lattice and the values at the pixels on the paths are changed. The first method, which was introduced by Strebelle (2002), works locally, uses conditional distributions (c.d.) for the new value at a pixel x given the values at n pixels in the neighborhood of x . The c.d.’s come often from *training images*. The method can be seen as working with an “empirical Gibbs sampler”; if a suitable model would be available, the c.d. were given by the model.

The other method, called “reconstruction,” works globally. It uses summary characteristics as targets for the whole pattern, which come from training images or parts of the structure that has to be reconstructed, e.g., planar sections or outcrops. For this purpose not only is the variogram used but also other characteristics as, e.g., various contact distribution functions. The algorithm minimizes the sum of squared differences between the calculated and empirical targets via stochastic optimization techniques such as simulated annealing by changing the value of one pixel per step, see article ► “Simulated Annealing” and Arns et al. (2002); Ballani and Stoyan (2015); Chiu et al. (2013); and Peredo and Ortiz (2011). Both approaches can be made conditional, using

simply known values at some pixels, known from exploration or planar sections (outcrops) and fixed during the simulation.

Object models or germ-grain models are simulated by quite different methods (Hauge et al. 2017; Pyrcz and Deutsch 2014), see Holden et al. (1998) for mathematical details. Starting from some initial configuration, the objects (lobes, channels, etc.) are removed and/or added to the system, following some rules for the mutual spatial relationships of the objects. Also these simulations can be made conditional, which is rather complicated (Hauge et al. 2017).

Stereology

Stereology is the art of obtaining 3D information from planar or linear sections, in the larger scale by investigations in the geosciences from rock outcrops, geophysical measurements, or drill holes, at the small scale from polished sections. See the *article Stereology*. There is a series of mean-value formulas, from which two are presented here.

Volume Fraction

$$V_V = A_A = L_L = P_P \quad (8)$$

A stationary 3D structure with one phase of interest is considered, V_V denotes the part of space occupied by this phase. This volume fraction can be obtained by measuring the *area fraction* A_A in a planar section, or the *linear fraction* L_L in a linear section, or the *point fraction* P_P on a lattice of test points.

Specific Surface

$$S_V = \frac{4}{\pi} L_A = 2P_L \quad (9)$$

For a 3D stationary and isotropic surface process S_V denotes the specific surface, mean surface area per unit volume. It can be obtained by measuring the *line density* L_A in a planar section (the mean length of section profiles from surface pieces per unit area) or the *specific number* P_L of intersection points of test line and surface pieces per length unit.

Summary

Geomathematics largely studies random geometrical structures. Thus stochastic geometry is potentially an important discipline in this area. It offers ideas that can aid in systematizing geomathematical knowledge and methods. At present stochastic geometry is dominated by applications in materials science, so systematic work is needed to adapt it for use in the geosciences.

It may be fruitful to add stochastic geometry to the general body of theory for geomathematics. The fact that most models

of stochastic geometry assume stationarity and isotropy is a difficult problem (as also in classical geostatistics). Real geological structures can rarely be modeled this way; this is a general problem of spatial statistics.

Biography

Dietrich Stoyan is a German mathematician who has worked mainly in geostatistics, spatial statistics, and stochastic geometry. He was born in Berlin in 1940 and grew up in the Halberstadt region in East Germany. Stoyan studied mathematics from 1959 to 1964 at the Technical University of Dresden, and then went to Freiberg in Saxony, where he has

lived since then. Initially, he worked in an institute for industrial research, where he applied geostatistical models to problems of lignite exploration. He received his PhD in 1967 (Dr.-Ing.) at the Bergakademie Freiberg (BAF, the worldwide oldest higher mining school) and completed his habilitation in mathematics at BAF in 1975. In 1976, he became a lecturer (Dozent) for mathematics at BAF. After the political changes in Europe and the German reunification, Dietrich Stoyan served as President (Rector) of the BAF from 1991 to 1997, which was renamed “Technische Universität Bergakademie Freiberg” at that time.

Dietrich Stoyan’s field of work is applied stochastics. He started in queueing theory and later turned to stochastic geometry and spatial statistics. He is an author or coauthor of books on stochastic geometry and point process statistics which are standard references. These books and many of his papers describe the geometry of geological phenomena by mathematical models from stochastic geometry, such as tectonic faults along oceanic rift zones or karst structures. At the first World Congress of the Bernoulli Society held at Tashkent in 1986, Dietrich Stoyan gave an invited lecture on “Stochastic Geometry in Geology”. He created a series of models for point processes and random sets and developed various methods in spatial statistics, especially for marked point processes. He initiated the use of the pair correlation function in point process statistics, and together with his PhD student, André Tscheschel, he introduced the reconstruction method for point processes. He has performed statistical analyses of basalt columns’ geometry and the evolution of taxa in paleontology. In addition, he was able to clarify a difficult text by Georgius Agricola from the sixteenth century on mineral classification, using basic ideas of combinatorics. Four of Stoyan’s most important scientific publications are listed in the references (Stoyan and Stoyan 1994; Stoyan and Penttinen 2000; Illian et al. 2008; Chiu et al. 2013).

Stoyan holds honorary doctorates from the universities of Jyväskylä (Finland) and Technical University of Dresden (Germany). He is a member of the Academia Europaea, of the Leopoldina (National German Academy of Sciences), and of the Berlin-Brandenburg Academy of Sciences and is a Fellow of the Institute for Mathematical Statistics.

Stratigraphic Sequence

Katherine L. Silversides

Australian Centre for Field Robotics, Rio Tinto Centre for Mining Automation, The University of Sydney, Sydney, NSW, Australia

Definition

A stratigraphic sequence is a series of sedimentary rocks that are classified based on their stratal stacking patterns and stratigraphic relationships (Catuneanu 2017).

Introduction

A stratigraphic sequence is a series of rock layers formed in sedimentary depositional environments. The stacking patterns of the layers and their relationships are used in the interpretation and classification of individual sedimentary units. The boundaries are defined by contacts that mark distinct changes in the stratal stacking pattern between two units. Sequence stratigraphy can be used as a generic, process-based method for mapping and correlation within a sedimentary basin that is independent of the geological setting and data used. However, multiple different approaches to stratigraphic sequencing exist (Catuneanu 2017; Mitchum et al. 2002). Studying the stratigraphic sequence of a sedimentary basin can provide information about the distribution of source rocks, depositional environment, migration pathways and traps, and some information about therefore the properties of the individual units (Bjørlykke 2015; Dalrymple and Choi 2007).

In a stratigraphic sequence the units are collated into genetically related groups, with chronostratigraphically significant surfaces bounding each group. These surfaces are generally depositional discontinuities where there are breaks in the deposition of new material, and often erosion. They normally occur as nonconformities or angular unconformities and can cut through multiple units within the group. Igneous layers can also occur, as volcanic layers or intrusions. In comparison, the surfaces separating units within a group are generally conformable and mark changes in the material being deposited. The rate of deposition of individual units is dependent on both the rate of sediment accommodation (i.e., relative fall in sea level) and the sediment supply rate (Bjørlykke 2015; Diessel 2007; Mitchum et al. 2002; Posamentier 2002).

The type of sequence deposited also depends on the interplay between accommodation space and sediment supply (Fig. 1). Progradational deposition occurs when the sediment

Banded Iron Formation

Another example of stratigraphic sequences is banded iron formations (BIF). These are rock units that contain deposited thin layers that alternate between a chert or silica-based layer and an iron oxide layer, often magnetite dominated. These layers form on a large range of scales, ranging from submillimeter-scale bands to the macrobands that can be meters thick. BIF typically contain 20–40% iron and 40–50% silica. Other layers of materials such as shales or volcanic rock may also be present. BIF are commonly found in Precambrian sedimentary successions (3800–543 Ma); however, they are no longer deposited and therefore their formation cannot be directly observed. Additionally, BIF lack the textural features that are common in other stratigraphic sequences. Therefore, their method of formation is still debated. Their deposition is linked to significant changes in the composition of the Earth's atmosphere and oceans. As unaltered BIF can retain the chemical signatures of the seawater they precipitated from, they can be used to study ancient seawater composition. Where sections of the BIF have been enriched through supergene or hypogene processes, they form high-grade iron ore deposits (Mloszewska et al. 2015; Trendall 2005).

Summary

Stratigraphy sequences are layers of sedimentary rocks formed in various underwater depositional environments. They are interpreted and classified based on their relative relationships and contacts. The formation of each layer depends on multiple factors such as sediment source, sediment supply, sediment accommodation, and depositional environment. Examples of stratigraphic sequences include coal deposits, petroleum fields, and BIF.

Definition

Structuring element (SE) is the part of an image that operates on the image itself to obtain the shape/size information of the objects in the image.

Introduction

The utilization of earth's resources such as water, minerals, crops, and forest by human beings is increasing day by day (Campbell 1987). Due to this reason, scientists are motivated to monitor the resources on a temporal basis. The advantages of remote sensing such as spatial resolution, spectral resolution, radiometric resolution, and temporal resolution provide the information about the resources periodically (Lillesand et al. 2014). The information of resources is obtained in an image format by the remote sensing sensors.

An image consists of finite elements called pixels/patterns/pels (Campbell 1987). The pixel is a digital number (DN) with a value between 0 and 255 (0 to 2^8-1) for an 8-bit display system (Lillesand et al. 2014). The DNs in an image replicate the objects present in the area of interest. There exist various mathematical methods to operate on the pixels of an image to extract the information about the objects in the images. These methodologies contribute to important remote sensing image analysis approaches such as image segmentation, image classification, change detection, etc. (Lillesand et al. 2014). There exists a good literature survey in the domain of image segmentation, image classification, change detection, etc.

In the initial stage, the raw images are preprocessed using various preprocessing techniques for radiometric/geometric corrections (Campbell 1987). The preprocessed image is used to extract the information by applying the mathematical models. The images are processed through various approaches such as spatial domain, frequency domain, etc. Spatial domain is the most preferable approach in image analysis to extract the information from an image.

In the spatial domain, a filter/window/kernel is operated on the input image to get the information related to edges, boundaries, lines, and closed objects (Lillesand et al. 2014). The filtering techniques contribute to segment the information about the objects in the image to a finite level. In the direction of spatial domain analysis of images, a structuring element-based filtering was suggested to obtain the shape/size information of objects in digital images. A set theory-based approach is implemented in structuring element-based spatial filtering and the field of study was named mathematical morphology (MM) (Matheron 1975; Serra 1982).

Structuring Element

The structuring element is a microstructure of the set employed to perform morphological operations. The role of the structuring element (B) is to unravel the hidden morphological properties of the set (X) (Serra 1982). In general, set X is considered as the input image and B is a micro part of X and B operates on X .

The SE elements are categorized as flat, non-flat, and graph structures (Soille 1999). The main characteristics of structuring elements include shape, size, orientation, and symmetry as shown in Fig. 1.

A square SE of size 3×3 with the center element associated by eight of its neighbors (also called eight connectivity) is presented in Fig. 1a. Similarly, the rhombical SE with 4-connectivity is given in Fig. 1b. The square and rhombical SEs are symmetric about the center or origin, that is, the rotation of the SE on its origin will result in SE with change in values. The SE which is asymmetric about the origin (bottom right) is given in Fig. 1c. The structuring element (B) in a 2D plane (Z^2) can be a 3×3 square given as $B = \{(-1,-1), (-1,0), (-1,1), (0,-1), (0,0), (0,1), (1,-1),$

Structuring Element, Fig. 1 (a) Square (disc in eight connectivity grid), (b) rhombical (disc in 4-connectivity grid) in shapes of primitive size of 3×3 , symmetric about the origin, and (c) structuring element that is asymmetric about the origin (shown in parenthesis)

$(1,0), (1,1)\}$, the elements at the coordinates given in B are binary 1s. Similarly, the rhombic structuring element B in (Z^2) is given as $B = \{(-1,0), (0,-1), (0,0), (0,1), (1,0)\}$.

Characteristic Information of Structuring Element

SE possesses the characteristics like shape, size, orientation, and origin to perform the morphologic transformations on set X . Broadly, the SE is categorized as symmetric and asymmetric (Maragos and Schafer 1986). A symmetric template is defined as $B^s = [-b : b \in B]$, where B^s is obtained by rotating B by 180° on the plane and b is an element in B (Maragos 1989). In Fig. 1a, and 1b B is symmetric with respect to the origin with a size of 3×3 . In asymmetric SE, the symmetric property of B is not satisfied indicating that a 180° shift in B will not produce B . The asymmetric SE of size 3×3 is given as,

$$B = \begin{bmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{bmatrix} \quad (1)$$

Shape of Structuring Element

Different shapes of SEs are considered to extract the shape/size information of objects in an image (Maragos and Ziff 1990). The important shapes of SEs are square, rhombic, ball, line, etc. The square and rhombic SEs are given in Fig. 1a, b.

Decomposition of Structuring Element

The structuring element of higher connectivity can be decomposed to lower connectivity to obtain the finite level of details from the input image (Sagar 2013). In Fig. 2a, the square SE of 8-connectivity (Fig. 1a) is decomposed to line SE of 2-connectivity to obtain the lines located in 45° orientation from the input image. Similarly, the square SE with 8 connectivity is decomposed to SE with 1-connectivity to obtain the upper line details located at 135° (Fig. 2b) orientation in an image. The square SE is decomposed to rhombic SE (Fig. 2c) to obtain the finite details of the objects in an image.

to process the input image to obtain the information about the objects of different sizes and shapes.

Sums of Geologic Random Variables, Properties

G. M. Kaufman
Sloan School of Management, MIT, Cambridge, MA, USA

Definition

Politicians, policy analysts, and business representatives often ask earth scientists to provide personal probability judgments about uncertain geological quantities. Assessment of oil and gas in unexplored petroleum plays and basins is a recurring example. Few geologists can provide sharp coherent judgments about probabilistic dependencies and often rely

on Pearson type correlations, flawed measures of dependency in many settings. More sophisticated techniques are needed that assure coherence of probabilistic judgments about uncertain geological random quantities and that reduce geologists' cognitive load.

For economists, bureaucrats, and politicians, right-tail probabilities are often the most interesting feature of a probabilistic oil and gas assessment. What, for example, is the probability of finding at least one more giant field in a mature petroleum province? Lillestøl and Sinding-Larsen's (2017) study of giant fields based on 182 North Sea discoveries highlights the importance of accurate modeling of tail probabilities. Blondes et al. (2013a, b) offer a rationale for careful attention to dependencies:

In the Circum-Arctic aggregation of the 48 AUs, the 90-percent uncertainty interval for recoverable gas is 1,471, 2,009, or 3,515 tcf for assumptions of independence, assessor specified dependency (correlation), or total dependence respectively. Clearly, decision makers who rely on assessment results need accurate interval projections. Too broad an interval provides little information; too narrow an interval gives a false sense of precision.

A rich probabilistic finance and actuarial risk analysis literature explores properties of sums of random variables when only marginal distributions are available (Hoeffding 1940; Fréchet 1951). It offers methods for assuring coherence of geologists' personal probability judgements about uncertain geological quantities in the absence of empirical data.

Probabilistic assessments of oil and gas in unexplored petroleum plays and basins are recurring examples. In the absence of hard data geologists' personal judgments about marginal distributions of geologic attributes are, in the large, reasonably well calibrated. However, their personal judgments about dependencies among them are problematic. According to Chen et al. (2012) "...variable correlations are so common among geologic variables that ignoring their interdependence may lead to serious bias, affecting both the resulting resource potential estimation."

Section "[Preliminaries](#)" describes co-monotonicity and its role in computing upper and lower bounds on sums of random variables. Section "[Thumbnail Case Studies](#)" presents thumbnail sketches of three geologic case studies. Concluding remarks appear in section "[Concluding Remarks](#)."

Preliminaries

Define F_X to be the distribution function of a random vector $\mathbf{X} = (X_1, \dots, X_n)^t$ with domain $\mathbf{R}^n$ and marginal distributions F_i , $i = 1, \dots, n$. Set $F_X(\mathbf{x}) = \text{Prob}\{X_1 \leq x_1, \dots, X_n \leq x_n\}$.

Divide difficulties, and assume that each F_i is continuous and possesses a one-to-one inverse. Define the p^{th} fractile of X_i as the value in the domain of X_i such that $\text{Prob}\{X_i \leq x_p\} = p$ and its inverse as $F_i^{-1}(p) = x_i(p)$. In turn the p^{th} fractile of the sum

$S_n = X_1 + \dots + X_n$ is s_p such that $\text{Prob}\{S_n \leq s_p\} = p$ or $F_{S_n}^{-1}(p) = s_p$.

What conditions guarantee that fractiles are strictly additive? That is, for all $p \in (0, 1)$ $s_p = x_1(p) + \dots + x_n(p)$? Imposition of functional dependencies among $X_1, \dots, X_n$ is one route to sufficient conditions. Suppose that $X_1, \dots, X_n$ share a common domain D_X and consider n continuous invertible functions h_i , each with domain D_X . Suppose that $x_i = h_i(x_1)$ for all $x_i \in D_X, i = 2, \dots, n$. Then $\text{Prob}\{X_1 + h_2(X_1) + \dots + h_n(X_1) < s\}$. The omnibus function $g(x_1) = x_1 + h_2(x_1) + \dots + h_n(x_1), x_1 \in D_X$ is continuous and invertible so $\text{Prob}\{g(X_1) < s\} = \text{Prob}\{X_1 < g^{-1}(s)\}$. The p^{th} fractile of S_n is s_p such that $\text{Prob}\{g(X_1) < s_p\} = p$ or $\text{Prob}\{X_1 < g^{-1}(s_p)\} = p$ leading to $x_1(p) = g^{-1}(s_p)$. Equivalently $g(x_1(p)) = s_p$. Functional dependencies of this type are too strong to model most geological data. Co-monotonicity is a more flexible approach to modeling joint behavior of dependent random variables.

Definition The random vector $\mathbf{X} = (X_1, \dots, X_n)^T$ is co-monotonic if and only if $(X_1, \dots, X_n) =_d (F_1^{-1}(U), \dots, F_n^{-1}(U))$, U a uniform random variable with domain $(0, 1)$.

Here $=_d$ means agreement in distribution. Each element of a co-monotonic random vector is a function of a single random variable U so all elements of $\mathbf{X}$ exhibit strong positive dependency. McNeil et al. (2005) provide a more general definition: $\mathbf{X}$ is co-monotonic if and only if it agrees in distribution with a random vector, each of whose components is a nondecreasing function of a single random variable. If elements of $\mathbf{X}$ are co-monotonic increasing one element of $\mathbf{X}$ increases all others. Research Report 9914 Goovaerts et al. (2000) provides a readable account of properties of sums of co-monotonic random variables in an actuarial context. Deelstra et al. (2009) review co-monotonicity in financial economics.

Foreshadowing geologists' critique that some elements of $\mathbf{X}$ may be independent or possibly negatively dependent (rather rare), co-monotonicity provides upper and lower bounds on a sum of random variables with specified marginal distributions that embrace a wide range of dependence structures. When these bounds are tight, reasonable projections of probability distributions of aggregates can be computed using marginal distributions and certain conditional expectations (see section "Bounds" (3)).

Bounds

A random variable X precedes a random variable Y in convex order, denoted by $X \geq_{cx} Y$ if and only if $E(g(X)) \geq E(g(Y))$ for all real convex functions g for which expectations are finite. Kaas et al. (2009) use convex order to show that fractiles of co-monotonic random variables additive in the following sense: for any random vector $\mathbf{X} = (X_1, \dots, X_n)$

possessing marginal cumulative distribution functions $F_1, \dots, F_n$ and U a uniform $(0, 1)$ random variable

$$(X_1 + \dots + X_n) \leq_{cx} S_u \equiv F_1^{-1}(U) + \dots + F_n^{-1}(U). \quad (1)$$

If $S_u =_d F_1^{-1}(U) + \dots + F_n^{-1}(U)$ it follows immediately that the p^{th} fractile of S_u is $F_{S_u}^{-1}(p) = F_1^{-1}(p) + \dots + F_n^{-1}(p)$, all $p \in (0, 1)$. They point out that (1) is a supremum in convex order and a best bound for marginal distributions in a Fréchet space. If a random vector $\mathbf{X}$ with marginal distributions $F_1, \dots, F_n$ belong to a Fréchet space $\mathcal{F}_n$ the joint cumulative distribution function $\text{Prob}\{X_1 \leq x_1, \dots, X_n \leq x_n\}$ of $\mathbf{X}$ is bounded from above by $M_n \equiv \min\{F_1(x_1), \dots, F_n(x_n)\}$. Goovaerts et al. note that M_n is reachable in $\mathcal{F}_n$. For sums of elements of $\mathbf{X}$ introduction of a random Z such that distribution of each X_i given Z is known with certainty leads to refined upper and lower bounds. In a geologic context Z is interpretable as a latent (background) variable describing gross geologic characteristics of, for example, a petroleum assessment unit. The conditioning variable Z might be regression dependent on geologic attributes of an assessment unit and need not be scalar. These authors define $F_{X_i|Z}^{-1}(U)$ to be a random variable $f_i(U, Z)$ that for $(U, Z) = (u, z)$ assumes value $F_{X_i|z}^{-1}(u)$ and prove that for U uniform $(0, 1)$ and Z independent of U

$$(X_1 + \dots + X_n) \leq_{cx} S_u^* \equiv F_{X_1|Z}^{-1}(U) + \dots + F_{X_n|Z}^{-1}(U). \quad (2)$$

Jensen's inequality leads to a lower bound

$$E(X_1|Z) + \dots + E(X_n|Z) \leq_{cx} (X_1 + \dots + X_n). \quad (3)$$

Kaas et al. (2009) point out that (a) the random vector $E(X_1|Z) + \dots + E(X_n|Z)$ will not in general have marginal distributions $F_1, \dots, F_n$ and (b) if $E(X_1|Z), \dots, E(X_n|Z)$ are either jointly nonincreasing or nondecreasing functions of Z the LHS in (3) is a sum of co-monotonous random variables and $\text{Var}(E(X_i|Z)) < \text{Var}(X_i)$ unless $\text{Var}(E(X_i|Z)) = 0$. In order to compute the cdf of the LHS of (3), suppose that (b) obtains and each of the random variables $E(X_1|Z), \dots, E(X_n|Z)$ are nondecreasing functions of increasing $Z = z$. Write the lower bound as, $E(X_1|Z) + \dots + E(X_n|Z) = E(S|Z)$, and define $F_{E(X_i|Z)}(x) = \text{Prob}\{E(X_i|Z) \leq x\}$. They show that if the cdf of $E(X_i|Z)$ is continuous and increasing:

$$F_{E(X_1|Z)}^{-1}(F_{E(S|Z)}(x)) + \dots + F_{E(X_n|Z)}^{-1}(F_{E(S|Z)}(x)) = x, \quad (4)$$

a prescription for calculating a lower bound. The quality of (3) depends on the choice of model for Z . Kaas et al. (2002) and Goovaerts et al. (2000) demonstrate that (1) and (3) provide reasonable bounds on the cumulative distribution function of sums of dependent lognormal random variables. Comparison

of predictive distributions of undiscovered mineral resources derived by conventional methods with co-monotonic bounds on them is a promising avenue of research.

Thumbnail Case Studies

USGS Oil and Gas Resource Projections

Chen et al. (2013) describe the 1980 USGS assessment system called FASP (fast appraisal system for petroleum resources). FASP incorporates perfect positive correlation between micro-level reservoir attributes but allows specification of any positive correlation among play resources. Nevertheless, the USGS 2000 World Petroleum Assessment aggregates undiscovered resource volumes from assessment unit level to regional level using perfect correlation to add fractiles and arrive at regional level aggregates. Recognizing that at the global-level dependencies among large regional aggregates of resources are unlikely to be perfectly correlated they assign pairwise correlation 0.5 to each pair of eight regions (Klett et al. 2000). No sensitivity analysis of aggregate projections is given.

Many USGS assessment studies present tables of fractiles of individual assessment units and add fractiles to arrive at total resource fractiles. Fractile addition is justified by stating that “Fractiles are additive under assumption of perfect positive correlation.” Table 2 in “Assessment of Undiscovered Continuous Oil and Gas Resources in the Monterey Formation, San Joaquin Basin Province, California” USGS Fact Sheet 2015–3058 September 2015 and Table 2 in USGS Fact Sheet 2014–3082 “Assessment of Potential Shale-Oil and Shale-Gas Resources in Silurian shales of Jordan” September 2014 are examples. Chen et al. (2013) cite additional examples (Klett et al. 2000, 2004, 2005). It is easy to show that “perfect correlation” is not robust to variations in specification of functional forms of marginal distributions. Worse, addition of fractiles without careful attention to properties of the joint distribution of geological uncertain quantities leads to incoherence. On the other hand, mutual independence allows specification of arbitrary marginal probability distributions without affecting coherence but leads to unacceptably narrow probability projections of sums of oil and gas magnitudes.

A salient feature of Pearson’s correlation coefficient is that random variables X and Y possess correlation 1.0 or -1.0 only if X and Y are linearly dependent. Denuit and Dehaene (2003) point to a limiting case, a pair of normal random variables for which the variance of one member of the pair is zero. Then, if X and Y are jointly lognormal and $\log X$ is a linear function of $\log Y$, the Pearson correlation of $\log X$ and $\log Y$ is either 1.0 or -1.0 . However, the Pearson correlation of

X and Y is less than 1.0. These authors provide a more nuanced treatment. Suppose F_1 and F_2 are marginal cumulative distribution functions of X and Y , respectively, each concentrated on $(0, \infty)$ and U is a uniform random variable independent of X and Y . Using super-modularity, they prove that if F_1 and F_2 lie in a Fréchet space, the Pearson correlation coefficient $r(X, Y)$ of X and Y is bounded by

$$\frac{\text{Cov}(F_1^{-1}(U), F_2^{-1}(1-U))}{\sqrt{\text{Var}(X)}\sqrt{\text{Var}(Y)}} \leq r(X, Y) \leq \frac{\text{Cov}(F_1^{-1}(U), F_2^{-1}(U))}{\sqrt{\text{Var}(X)}\sqrt{\text{Var}(Y)}} \quad (5)$$

so perfect correlation is not achievable. They also prove that it is possible for a pair of co-monotonic lognormal random variables to have pairwise correlation close to zero, contradicting the intuitive notion that small correlation implies weak dependence.

These authors document several important features of Kendall’s τ and Spearman’s ρ . (Spearman’s ρ is at the center of Iman and Conover’s method deployed in the USGS (2013) CO_2 sequestration study to compute predictive probability distributions of aggregates). First, both are invariant with respect to strictly monotone transformations. Second, when one variable is a nondecreasing (nonincreasing) transformation of the other they equal 1 (or -1) at the Fréchet upper (resp. lower) bound. They note that at a value of 1.0 or -1.0 , Kendall’s τ and Spearman’s ρ achieve Fréchet bounds. Kendall’s τ and Spearman’s ρ are more desirable measures of association for non-normal multivariate distributions than Spearman’s r because the latter does not share Kendall and Spearman’s correlation invariance properties which come into play in Iman and Conover’s method. Denuit and Dehaene prove the nonobvious fact that if positively or negatively quadrant-dependent random pairs are jointly uncorrelated, they are mutually independent.

“Perfect correlation” as an omnibus argument for adding fractiles has many pitfalls. Co-monotonic bounds on random sums are a conceptually satisfactory alternative.

USGS Probabilistic Assessment of CO_2 Storage Capacity

The USGS probabilistic assessment of CO_2 sequestration in mature petroleum reservoirs (Blondes et al. 2013a, b) is based on both micro- and macro-assessments. Their macro-assessment aggregates storage assessment units (SAUs) at basin, regional, and national levels. An objective was to take into account dependencies among assessment units arising from “overlap of geologic analogs, assessment methods and assessors” using individual SAU marginal probability distributions and “. . . a correlation matrix obtained by expert

elicitation describing interdependencies between pairs of SAUs.” The correlation matrix dimension is 192×192 . Because a menagerie of marginal distributions – Beta-PERT, lognormal, truncated lognormal – were deployed at the micro-level, the use of standard multivariate distribution theory is not appropriate. Dependencies among storage capacity magnitudes rest on an innovative distribution free method developed by Iman and Conover (1982) allowing marginal distributions and dependencies to be estimated from distinct data sets.

How to aggregate from basin, to region, and then to a national scale? A single stage using the correlation matrix for all SAUs in the study? Or successively aggregate subsets of SAUs in multiple stages? Blondes et al. (2013b) conclude that:

Although the single-stage approach requires determination of significantly more correlation coefficients, it captures geologic dependencies among similar units in different basins and it is less sensitive to fluctuations in low correlation coefficients than the multiple stage approach.

Successive aggregation in multiple stages drastically reduces the number of pairwise correlations elicited from geologists at the expense of requiring each assessor to appraise pairwise correlations of sums of assessment unit magnitudes. Appraisal of resource volumes in an individual SAU are more likely to be well calibrated than direct appraisal of a sum of SAU volumes (Kaufman et al. 2017).

Cupolas and Oil and Gas Resource Assessment

Chen et al. (2013) emphasize that at an assessment micro-level, reservoir attributes such as porosity, permeability, pressure, and temperature are often decisively dependent and that empirical data suggest dependencies are present among more aggregate assessment units in mature provinces. They argue that a basin’s tectonic framework exerts “strong geographic control” over many geological features and leads to geographic and spatial dependencies and that because plays in a given basin share “. . . petroleum system elements, such as source rocks, regional top seal, migration fairways, timing, regional tectonics for trap formation, and accumulation preservation factors.” They are the first to use copulas in this setting.

Sklar (1959) proved that subject to mild restrictions a multivariate cumulative distribution can be mapped to a joint cumulative distribution of uniform random variables called a cupola. As with Iman and Conover’s method, cupolas allow marginal distribution shapes to be computed from data sets distinct from those used to estimate dependency structure.

Suppose as in section “Thumbnail Case Studies” above that F_X is the distribution function of a random vector $\mathbf{X} = (X_1, \dots, X_n)^t$ with domain $\mathbf{R}^n$ and marginal cumulative

distributions F_i , $i = 1, \dots, n$. Let $\mathbf{U}_n = (U_1, \dots, U_n)$ be a vector of independent uniform $(0, 1)$ random variables and $\mathbf{u}_n = (u_1, \dots, u_n)$ be a realization of $\mathbf{U}_n$. Then with $u_i = F_i(x_i)$, $i = 1, \dots, n$ $\text{Prob}\{X_1 \leq x_1, \dots, X_n \leq x_n\} = \text{Prob}\{U_1 \leq u_1, \dots, U_n \leq u_n\}$.

Definition $C(u_1, \dots, u_n) = \text{Prob}\{U_1 \leq u_1, \dots, U_n \leq u_n\}$ is the cupola of F_X .

Set $dF_i = f_i$, $i = 1, \dots, n$ and $dC(u_1, \dots, u_n) = c(u_1, \dots, u_n)du_1 \dots du_n$. The joint density of $\mathbf{X}$ can be written as $c(u_1, \dots, u_n) \times f_1(x_1) \times \dots \times f_n(x_n)$. The term c in the joint density captures the dependency structure of elements of $\mathbf{X}$. Because $\text{Prob}\{X_1 \leq x_1, \dots, X_n \leq x_n\} = \text{Prob}\{U_1 \leq u_1, \dots, U_n \leq u_n\}$ a procedure for generating samples from C produces samples of $\mathbf{X}$ by inversion of $u_i = F_i(x_i)$, $i = 1, \dots, n$.

Computation requires choice of a cupola functional form. Chen et al. chose the bivariate normal cupola, a popular choice closely tied to standard multivariate normal distribution theory.

Their regional resource assessment of the Canadian Arctic’s Beaufort-McKenzie Basin analyzes 48 “significant” oil and gas discoveries containing 53 distinct accumulations in three major petroleum systems. Empirical data allows estimation of pairwise correlations among reservoir attributes – area, porosity, oil saturation, and net pay. The authors treat geologic risk factors as probabilistically independent because the data does not allow empirical estimation of dependencies among them. Dependencies are restricted to play reservoir volume attributes. In turn these dependencies impact of the distribution of total resource volumes.

Four plays illustrate how to incorporate dependencies among individual play resources. No method for eliciting geologists’ judgments about dependencies between plays is described. However, the authors assert that between play correlations are large because all four plays share the same source rock and petroleum system. They call attention to substantial differences between total ultimate oil resource medians under the assumption of independence and under the assumption of within and between play correlations: the latter is 1.6 times the former.

In sum, to be realistic, probabilistic appraisal of oil and gas resources in unexplored and partially explored regions must account for multiple sources of dependencies. Cupolas are useful for doing so.

Concluding Remarks

In the absence of empirical data that allows resolution of the vexing problem of how to address probabilistic dependencies

among and between elements of large sets of geologic random variables data, we need methods that refocus and streamline expert geological judgment inputs as well as analytical methods for modeling dependencies that go beyond pairwise correlation and its cousins.

Support vector network

Definition

Support vector machine (SVM) is a supervised machine learning algorithm applied to data classification and regression. Starting from the 1990s early formalization presented by Cortes and Vapnik (1995), support vector machine (SVM) has been highlighted as a machine learning method widely applied in several research areas. Some reasons for all attention and focus received by the SVM method, especially over the two first decades of the twenty-first century, are its solid theoretical basis and characteristics like data distribution independence, simple algorithm architecture, moderate computational complexity, and excellent generalization ability.

A Formalization for Linearly Separable Data

The SVM method comprises to define a linear discriminant function $g(\mathbf{x}) = \mathbf{w}^T \mathbf{x} + b$ able to distinguish a set of vectors linearly separable $\mathcal{D} = \{(\mathbf{x}_i, y_i) \in \mathcal{X} \times \mathcal{Y} : i = 1, \dots, m\}$ between the classes ω_1 , when $y_i = +1$, and ω_2 , if $y_i = -1$. The sets $\mathcal{X} \subseteq \mathbb{R}^n$ and $\mathcal{Y}$ represent the attribute (vector) space of the data and a set of class indicators, respectively. Moreover, the function g delivers the largest separation margin between the pair of classes.

Behind the process of determining the maximum margin separation hyperplane lies the simple concept of distance from a point to line (Theodoridis and Koutroumbas 2008; Webb and Copsey 2011). Knowing that the distance from a given vector (point) $\mathbf{x}_i$ to the separation hyperplane (line) $g(\mathbf{x}) = 0$ is computed through $\frac{|g(\mathbf{x}_i)|}{\|\mathbf{w}\|}$, when rescaling $\mathbf{w}$ to make $\mathbf{x}_u \in \omega_1$ and $\mathbf{x}_v \in \omega_2$ from $\mathcal{D}$, identified as the closest points to $g(\mathbf{x}) = 0$, has distance equal to one from such hyperplane, it is modeled the following optimization problem which solution leads to $\mathbf{w}$ and b parameters assigned to the largest separation margin hyperplane:

$$\begin{aligned} \min_{\mathbf{w}, b} \quad & \frac{1}{2} \mathbf{w}^T \mathbf{w} \\ \text{subject to : } & y_i (\mathbf{w}^T \mathbf{x}_i + b) \geq 1, i = 1, \dots, m \end{aligned} \quad (1)$$

Figure 1a depicts the geometric relations of the maximum margin hyperplane. Vectors located at the limits of separation margin (i.e., $g(\mathbf{x}) = \pm 1$) are the ones responsible to define the optimum hyperplane, the so-called support vectors.

The optimization problem that allows reaching the maximum margin hyperplane is a convex function with linear constraints. Consequently, the Lagrangian multipliers approach allows solving such optimization problems more conveniently. Adopting this approach, solve (1) is equivalent to optimize the following:

$$\begin{aligned} \max_{\lambda} L_D(\lambda) &= \sum_{i=1}^m \lambda_i - \frac{1}{2} \sum_{i=1}^m \sum_{j=1}^m \lambda_i \lambda_j y_i y_j \mathbf{x}_i^T \mathbf{x}_j \\ \text{subject to : } &\begin{cases} \lambda_i \geq 0, & i = 1, \dots, m \\ \sum_{i=1}^m \lambda_i y_i = 0 \end{cases} \end{aligned} \quad (2)$$

where $\lambda_i \geq 0$; $i = 1, \dots, m$ are Lagrange multipliers.

The Lagrange multipliers that come after solving (2) allow computing the maximum margin parameters. While the vector $\mathbf{w}$ is equivalent to $\sum_{i=1}^m \lambda_i y_i \mathbf{x}_i$, the scalar b is computed after substitute $\mathbf{w}$ in $g(\mathbf{x}_i)$, where $\mathbf{x}_i$ is a support vector with $y_i = +1$, and consequently, $\mathbf{w}^T \mathbf{x}_i + b = 1$.

Additionally, beyond providing a simpler way to compute the optimum parameters, the inner product in Eq. 2 (i.e., $\mathbf{x}_i^T \mathbf{x}_j$), may also be replaced by a *kernel function*.

As a consequence of the obtained maximum margin hyperplane, rises the following discrimination rule:

$$g(\mathbf{x}) = \mathbf{w}^T \mathbf{x} + b \begin{cases} \geq 0 \Rightarrow \mathbf{x} \in \omega_1 \\ < 0 \Rightarrow \mathbf{x} \in \omega_2 \end{cases} \quad (3)$$

Formalization for Nonlinearly Separable Data

The previous formulation assumes a classification problem where the vectors/data are linearly separable. However, it is usual that the classification problems are not restricted to such situations. In order to deal with nonlinearly separable data, slack variables $\xi_i \geq 0$, $i = 1 \dots, m$ are included to make valid the statements:

- (i) If $\mathbf{x}_i \in \omega_1$, then $g(\mathbf{x}_i) = \mathbf{w}^T \mathbf{x}_i + b \geq +1 - \xi_i$
- (ii) If $\mathbf{x}_i \in \omega_2$, then $g(\mathbf{x}_i) = \mathbf{w}^T \mathbf{x}_i + b \leq -1 + \xi_i$

Geometrically, the slack variables represent the displacement observed over the wrongly classified data concerning its respective separation margin limit, as shown in Fig. 1b.

The term $C \sum_{i=1}^m \xi_i$ is included in the objective function of Eq. (1) to embrace a cost due to the nonlinear separable data. Such term counts and penalizes the wrong classifications by the separation hyperplane. $C > 0$ is a regularization parameter. Consequently, the optimization problem formulated to deal with nonseparable data differs from Eq. (2) only regarding its constraints; this is:

$$\begin{aligned} \max_{\lambda} & \sum_{i=1}^m \lambda_i - \frac{1}{2} \sum_{i=1}^m \sum_{j=1}^m \lambda_i \lambda_j y_i y_j \mathbf{x}_i^T \mathbf{x}_j \\ \text{subject to : } &\begin{cases} 0 \leq \lambda_i \leq C, & i = 1, \dots, m \\ \sum_{i=1}^m \lambda_i y_i = 0 \end{cases} \end{aligned} \quad (4)$$

After solving Eq. (4), the parameter $\mathbf{w}$ is computed similarly as made for the linearly separable case. b may be calculated by substituting a support vector with null slack variable into the relations (i) or (ii).

Support Vector Machines, Fig. 1 Representation, in both linearly and nonlinearly separable cases, for the separation hyperplane parameters, margin, and support vectors (circulated). (a) Linearly separable data. (b) Nonlinearly separable data

Kernel Functions

The previous formulations show how the separation hyperplane is determined in the SVM method. Nonetheless, when the data is highly nonlinear, the use of linear surfaces to separate such data do not make sense. Alternatively, the nonlinear data may be remapped from the original attribute space to a new *feature space* where the separation may be better.

Such remapping process may occur implicitly after substitute the inner products $\mathbf{w}^T \mathbf{x}_i$ and $\mathbf{x}_i^T \mathbf{x}_j$ in (3) and (4) by a function $K(\cdot, \cdot)$ which attains the conditions of *Mercer's theorem* (Theodoridis and Koutroumbas 2008):

Mercer's theorem Let $\mathbf{u}, \mathbf{v} \in \mathcal{X} \subseteq \mathbb{R}^n$ and $\phi(\cdot)$ a mapping $\mathbf{u} \mapsto \phi(\mathbf{u}) \in \mathcal{H}$, where $\mathcal{H}$ is a Hilbert space. The inner product $\phi(\mathbf{u})^T \phi(\mathbf{v})$ it is equivalent to a continuous and symmetric function $K(\mathbf{u}, \mathbf{v})$ that satisfies:

$$\int_{\mathcal{X}} \int_{\mathcal{X}} K(\mathbf{u}, \mathbf{v}) h(\mathbf{u}) h(\mathbf{v}) d\mathbf{u} d\mathbf{v} \geq 0 \quad (5)$$

for a given $h(\mathbf{u})$, such that:

$$\int_{\mathcal{X}} h(\mathbf{u})^2 d\mathbf{u} < +\infty \quad (6)$$

As consequence of this theorem, for any function $K(\cdot, \cdot)$ that satisfies (5) and (6), it is possible to affirm there is a vector space where $K(\cdot, \cdot)$, a so-called kernel function, represents an inner product.

Although the Mercer's theorem gives sufficient condition to define functions that stands for an inner product into a vector space, this space is unknown. Consequently, it is not possible to define $\phi(\cdot)$ from $K(\cdot, \cdot)$. Moreover, check if a given function $K(\cdot, \cdot)$ attains the conditions of Mercer's theorem may comprise a nontrivial task (Schölkopf and Smola 2002).

Examples of frequently adopted kernels are the radial basis function (RBF) ($K_{\text{RBF}}(\mathbf{x}_i, \mathbf{x}_j) = e^{-\gamma \|\mathbf{x}_i - \mathbf{x}_j\|^2}$), Polynomial ($K_{\text{Pol}}(\mathbf{x}_i, \mathbf{x}_j) = (\gamma \mathbf{x}_i^T \mathbf{x}_j + \alpha)^q$) and Sigmoid ($K_{\text{sigm}}(\mathbf{x}_i, \mathbf{x}_j) = \tanh(\gamma \mathbf{x}_i^T \mathbf{x}_j + \alpha)$) functions, where $q \in \mathbb{N}^*$ and $\gamma, \alpha \in \mathbb{R}_+^*$ are parameters. The usual inner product between vectors is referred as linear kernel function ($K_{\text{Linear}}(\mathbf{x}_i, \mathbf{x}_j) = \mathbf{x}_i^T \mathbf{x}_j$).

As a reference, Fig. 2 depicts the separation surfaces defined by the Linear and RBF kernel functions when applied to a nonlinear separable training set. The flexibility provided by the RBF kernel delivers a better adherence to the data.

Multiclass Strategies

According to the previous discussions, the classification process was restricted to a pair of classes. However, practical problems may involve a larger number of classes. Multiclass strategies are usually employed to deal with such a restriction.

Support Vector Machines, Fig. 2 Separation hyperplanes using linear and RBF kernels. (a) Linear. (b) RBF

Support Vector Machines, Fig. 3 Decision regions using different multiclass strategies and kernel functions. (a) Linear ($C = 100$) – OVO. (b) RBF ($C = 100, \gamma = 0.5$) – OVR

Among several proposes found in the literature, the one-versus-rest (OVR) and one-versus-one (OVO) are the most commons multiclass strategies.

The OVR strategy, supposing a classification problem involving c classes, defines c separation hyperplanes. Each hyperplane is designed to separate one “reference” class from the other classes. Consequently, the final decision about the class of a given vector is made according to the hyperplane the delivers a classification concerning its reference class with the biggest vector-to-hyperplane distance.

On the other hand, for the OVO strategy, a problem with c classes unfolds into $c(c - 1)/2$ hyperplanes (i.e., the number of combinations of c elements taken 2 at a time) responsible for separating a pair of classes. Since the vectors may be assigned to the same class several times, the final decision is made according to the most assigned class (i.e., a majority voting scheme).

Figure 3 depicts the decision regions defined through a training set that simulates a multiclass classification problem. Distinct strategies and kernels tend to imply different decision regions.

Regression with SVM

Intuitive changes in the initial formulation may adapt the SVM method for data regression purpose. Given the set of observations $\{(\mathbf{x}_1, y_1), \dots, (\mathbf{x}_m, y_m)\} \subset \mathcal{X} \times \mathbb{R}$, the following relations are stated:

$$\begin{aligned} \text{(iii)} \quad & (\mathbf{w}^T \mathbf{x}_i + b) - y_i \leq \epsilon + \xi_i, \\ \text{(iv)} \quad & y_i - (\mathbf{w}^T \mathbf{x}_i + b) \leq \epsilon + \hat{\xi}_i, \end{aligned}$$

where $\xi_i, \hat{\xi}_i \geq 0$ are slack variables that control the positive and negative divergences with amplitude above to $\epsilon \in \mathbb{R}_+$.

As consequence of (iii) and (iv), $g(\mathbf{x}) = \mathbf{w}^T \mathbf{x} + b$ comprises a regression model that when applied to $\mathbf{x}_i$ should reveal a deviation from the expected result y_i . The computing of ξ_i and $\hat{\xi}_i$, for $i = 1, \dots, m$, that provides the smallest deviation between $g(\mathbf{x}_i)$ and y_i is obtained by:

$$\begin{aligned} \max_{\lambda_i, \hat{\lambda}_i} \quad & \left\{ -\frac{1}{2} \sum_{i=1}^m \sum_{j=1}^m (\lambda_i - \hat{\lambda}_i) (\lambda_j - \hat{\lambda}_j) \mathbf{x}_i^T \mathbf{x}_j + \right. \\ & \left. \sum_{i=1}^m (\hat{\lambda}_i - \lambda_i) y_i - \epsilon \sum_{i=1}^m (\hat{\lambda}_i + \lambda_i) \right\} \\ \text{subject to:} \quad & \begin{cases} \sum_{i=1}^m (\lambda_i - \hat{\lambda}_i) = 0 \\ 0 \leq \lambda_i, \hat{\lambda}_i \leq C/m; i = 1, \dots, m \end{cases} \end{aligned} \quad (7)$$

where λ_i and $\hat{\lambda}_i$ are Lagrange multipliers.

The solution from Eq. (7) allows defining $\mathbf{w} = \sum_{i=1}^m (\hat{\lambda}_i - \lambda_i) \mathbf{x}_i$. Consequently, the regression model g it is rewritten as $g(\mathbf{x}) = \sum_{i=1}^m (\hat{\lambda}_i - \lambda_i) \mathbf{x}_i^T \mathbf{x} + b$, where b may be estimated as the average of $|g(\mathbf{x}_i - y_i)| < \epsilon$ considering only the pairs $(\mathbf{x}_i, y_i)$ such that $0 < \lambda_i < C$ or $0 < \hat{\lambda}_i < C$.

Support Vector Machines, Fig. 4 Regression models provided by SVM and distinct kernel functions and parameters. (a) Linear ($C = 100$). (b) RBF ($C = 100, \gamma = 0.1$). (c) RBF ($C = 100, \gamma = 1.0$)

Furthermore, it is worth to mention that the product $\mathbf{x}_i^T \mathbf{x}$ in g may be substituted by a convenient kernel function.

Considering a data set simulated by $f(x) = x^2 \sin(x) + x\zeta$, with $\zeta \sim \mathcal{N}(0, 1)$ and $x \in \mathbb{R}$, Fig. 4 exhibits regression models achieved using different kernels and parameters. A linear approximation is obtained using the Linear kernel. More adherent adjusts are provided using the RBF kernel, where it is also possible identifying the influence of γ parameter in the final models.

Quadratic Optimization, Parametrization, and the Computational Cost

The SVM method shows the advantages in comparison to other methods like those based on the gradient descent or adjust of probability distributions. In such examples, the learning process may be sensitive to initialization parameters that lead to suboptimal results. Conversely, the learning process of the SVM method is characterized by the optimization

of convex (quadratic) functions, which implies unique and explicit solutions Burges and Crisp (2000).

However, weakness comes from the aforementioned optimization problem, specifically regarding the number of terms in the objective function that increases in quadratic proportion to the number of training vectors, consequently demanding a high computational cost. Such peculiarity may be critical in the face of large training data sets. Over the years, this fact motivated the development and improvement of new algorithms to make the SVM training faster and light. Examples of algorithms designed for this purpose are the *sequential minimal optimization* (SMO) (Platt 1999), *SVM^{Light}* (Joachims 1999), *chunking* (Vapnik and Kotz 2006), and LibSVM (Chang and Lin 2011).

Other factors that influence the computational cost are the adopted penalty (C) and kernel parameters. The use of parameters that yields a low computational cost may impair the learning and generalization abilities. In this context, we may conclude that although the optimization algorithm is a relevant element in the SVM training, and sufficient training data and the selected parameters are also important in the learning process.

Summary

SVM is a theoretically attractive, versatile, and powerful supervised method for data classification and regression.

t-Distributed Stochastic Neighbor Embedding

Mehala Balamurali

Australian Centre for Field Robotics, University of Sydney,
Sydney, NSW, Australia

Definition

t-Distributed stochastic neighbor embedding (t-SNE) method is an unsupervised machine learning technique for nonlinear dimensionality reduction to visualize high-dimensional data into low dimensional space. This method was introduced by Van der Maaten and Hinton in 2008. Among the many other dimensionality reduction approaches that are nonlinear methods which project the high-dimensional data into low-dimensional space by keeping nonsimilar data points far apart but are not capable for visualizing the high-dimensional real data, the nonlinear mapping by t-SNE groups the similar datapoints closer and therefore preserves the structure of the high dimensional in the low-dimensional space. Therefore, t-SNE is able to visualize the natural clusters in low dimensional space. Hence t-SNE is considered as a popular visualization tool that supports cluster analysis of high-dimensional data. t-SNE method has been used in many research fields.

Implementation

The t-SNE algorithm was proposed as a variation of stochastic neighbor embedding (SNE) (Hinton and Roweis 2002) to overcome the problem of optimizing the cost function. SNE converts the distance between the similar data points in high dimensional into conditional probabilities.

Given the data points x_i and x_j , the conditional probability, $p_{j|i}$, is given by Eq. 1 such that x_i would pick x_j as its neighbor if neighbors were picked in proportion to their probability

density under a Gaussian centered at x_i (Fig. 1). In Eq. 1, the distance between x_i and x_j is calculated in Euclidean distance, and the σ_i is the variance of the Gaussian that is centered on datapoint x_i . $p_{j|i} = 0$

$$p_{j|i} = \frac{\exp\left(\frac{-\|x_i - x_j\|^2}{2\sigma_i^2}\right)}{\sum_{k \neq i} \exp\left(\frac{-\|x_i - x_k\|^2}{2\sigma_i^2}\right)} \quad (1)$$

The variance, σ^2 , of the Gaussian kernel is calculated using a binary search such that the entropy, $(P_i) = -\sum_j P_{j|i} \log_2 P_{j|i}$, of the probability distribution over all the data points is equal to $\log_2(Perp)$, where *Perp* is the user-specified perplexity (Van der Maaten and Hinton 2008).

In the low-dimensional space, SNE computes a similar conditional probability for map points y_i and y_j (corresponding to the two data points, x_i and x_j) using another Gaussian kernel with variance equaling 1/2

$$q_{j|i} = \frac{\exp\left(-\|y_i - y_j\|^2\right)}{\sum_{k \neq i} \exp\left(-\|y_i - y_k\|^2\right)} \quad (2)$$

and $q_{i|i} = 0$ by definition. The conditional probabilities, $p_{j|i}$ and $q_{j|i}$, should be equal; if the map points, y_i and y_j , exactly represent the similarity between the high-dimensional data points, x_i and x_j .

SNE thus arranges map points in the low-dimensional space to minimize the discrepancy between $p_{j|i}$ and $q_{j|i}$ measured by the Kullback-Leibler (KL) divergence considering all data points. The cost function to be minimized is

$$C = \sum_i KL(P_i | Q_i) = \sum_i \sum_j p_{j|i} \log \frac{p_{j|i}}{q_{j|i}} \quad (3)$$

where P_i is the conditional probability distribution of data point x_i with respect to all other data points and Q_i is the

t-Distributed Stochastic Neighbor Embedding, Fig. 1 Conditional probability of data points in high and low dimensional space

conditional probability distribution of map point y_i over all other map points. As the KL is asymmetric, Eq. 3 uses a large cost to place nearer data points in high dimensional to keep them furthest in low dimensional and use low cost to place widely separated data points in high dimensional to nearer in low dimensional map. The cost function is minimized through various optimization methods such as gradient descent. The gradient of the cost function of SNE is

$$\frac{\delta C}{\delta y_i} = 2 \sum_j (P_{ji} - q_{ji} + P_{ij} - q_{ij}) (y_i - y_j) \quad (4)$$

Furthermore, the momentum used in SNE drives the optimization faster and evade local optima.

$$y^{(t)} = y^{(t-1)} + \eta \frac{\delta C}{\delta y} + \alpha(t) (y^{(t-1)} - y^{(t-2)}) \quad (5)$$

where (t) is the momentum at iteration t ; $y(t)$ is the solution at iteration t ; and η is the learning rate.

t-SNE is introduced to overcome the downsides of SNE; cost function is difficult to optimize and the crowding problem, by symmetrizing the cost function and incorporating student t -distribution to calculate the resemblances of data points in low dimension. Hence the t-SNE is described by the dataspace, map space, and cost function by Eqs. 6, 7, and 8:

$$p_{ij} = \frac{\exp(-\|x_i - x_j\|^2 / 2\sigma_i^2)}{\sum_{k \neq i} \exp(-\|x_k - x_i\|^2 / 2\sigma_i^2)} \quad (6)$$

$$q_{ij} = \frac{(1 + \|y_i - y_j\|^2)^{-1}}{\sum_{k \neq i} (1 + \|y_k - y_i\|^2)^{-1}} \quad (7)$$

$$C = KL(P \parallel Q) = \sum_{j \neq i} p_{ij} \log \frac{p_{ij}}{q_{ij}} \quad (8)$$

The gradients descent is given by

$$\frac{\delta C}{\delta y_i} = 4 \sum_j (P_{ij} - q_{ij}) (y_i - y_j) (1 + \|y_i - y_j\|^2)^{-1} \quad (9)$$

Perplexity, learning rate and number of iterations are some of the hyper parameters that control the clusters in the t-SEN reduced coordinates. Among them perplexity is the most influential factor, and therefore the results of t-SNE are fairly robust to perplexity change (Fig. 2). In Eq. 3, small value and larger values of σ^2 determine the pairs x and x with small distance and large distance, respectively. Though a recommended range for perplexity is 5–50, a frequently used perplexity is 30.

Algorithm 1: Simple version of t-Distributed Stochastic Neighbor Embedding

Data: data set = $\{x_1, x_2, \dots, x_{n1}\}$,

cost function parameters: perplexity $Perp$,

optimization parameters: number of iterations T , learning rate η , momentum $\alpha(t)$.

Result: low-dimensional data representation $Y^{(T)} = \{y_1, y_2, \dots, y_n\}$.

t-Distributed Stochastic Neighbor Embedding,

Fig. 2 (a) The original clusters and plots (b–f) show the impact of perplexity on resulting embedding with the chosen perplexity values 2, 5, 30, 50, and 100, respectively. Each plot was produced by 5000 runs with epsilon 10 (Wattenberg et al. 2016)

 compute low-dimensional affinities q_{ij} (using Eq. 7)
 compute gradient $\frac{\partial C}{\partial y}$ (using Eq. 9)
 set $y^{(t)} = y^{(t-1)} + \eta \frac{\partial C}{\partial y} + \alpha(t)(y^{(t-1)} - y^{(t-2)})$
end
end

Algorithm Vander Maaten and Hinton (2008)

Application of t-SNE in Cluster Delineation

Application of t-SNE was widely studied in biology, and the results showed a more accurate representation of multidimensional data when it is embedding into low dimensional t-SNE coordinates. It is the key technique used in two tools: viSNE and automatic classification of cellular expression by nonlinear stochastic embedding (ACCENSE), for analyzing mass cytometry data in

immunology (Amir et al. 2013; Shekhar et al. 2014). t-SNE-based algorithm is found as one of the techniques that can better represent the similarities between the cell type clusters (Saeys et al. 2016). In recent years t-SNE has become a popular method for visual exploration of scRNA-seq data because t-SNE can create well separated clusters in 2D coordinates of the high-dimensional data that can be well clustered (McInnes et al. 2018; Becht et al. 2019). In 2019, Aizarani et al. (2019) and Dobie et al. (2019) used t-SNE to highlight the important liver cell partitions by mapping the single-cell transcriptomes from liver tissue. Kobak and Berens (2019) showed that the initialization with PCA and larger perplexity preserves the macroscopic structure and mesoscopic structure of the gene data, respectively. Hyper-spectral images with the thousands of spatial-spectral dimensionalities often suffer from unwanted feature spectra that correspond to the same ground truth. t-SNE was successfully applied in this domain to map a nonlinear representation of spectral features in a lower 2D space (Pouyet et al. 2018, Zhang et al. 2018).

In 2016, t-SNE was introduced to embed mineral and waste exploration datasets into 2D t-SNE coordinate (Balamurali and Melkumyan 2006). The study showed that t-SNE can preserve more information in the data compared to other dimensionality methods PCA, LLE, and kPCA (Fig. 3). In addition, the authors applied spectral clustering on t-SNE

t-Distributed Stochastic Neighbor Embedding,

Fig. 3 Two-dimensional visualization on mineral and waste exploration dataset. The (d) 2D t-SNE embedding shows more distinct clusters than the (a) PCA, (b) kPCA and (c) LLE. Color bars show the Fe distribution. Blue and red dots show the waste and

coordinates to extract clusters using the t-SNE coordinates and the chemical distribution within each cluster showed meaningful geological domains (Fig. 4).

Later, this method was compared with other clustering methods, self-organizing map (SOM) and spanning-tree progression analysis of density-normalized events (SPADE), to study the material grouping (Balamurali et al. 2019) and to group potential distinct material domains (Figs. 5 and 6). Horrocks et al. in 2019 used t-SNE to study the process of rock hydration using geochemical data. In this study the authors compared the embedding results by t-SNE using all elements and subset of elements (selected features) and demonstrated that t-SNE using subset of features outperformed in differentiating altered and unaltered specimens. In 2021 t-SNE was employed for understanding spatial and temporal patterns of groundwater geochemistry (Liu et al. 2021). The results obtained using t-SNE on chemical data were encouraging. Overall, t-SNE was found to be capable of producing geochemical embeddings wherein external geological properties were reflected in the cluster or intra-cluster structure.

A novel technique EC-tSNE (ensemble clustering based t-distributed stochastic neighbor embedding) was proposed to minimize stochastic variation in the standard

t-SNE approach (Balamurali and Melkumyan 2020) and therefore consistently identified sub-geological regions that they were not previously known (Fig. 7). This study used cluster number optimization which measures the consistency of samples within cluster. The proposed approach also used the agglomerative clustering which increase the reliability of the results obtained from t-SNE and spectral clustering by reducing randomness. Hence the complete system seeks to find the most stable or dominant cluster. A recent study compared EC-tSNE with the robust estimator approach called MCD (minimum covariance determinant) in terms of their efficacy for outlier removal in multivariate geochemical data (Leung et al. 2019).

Summary

t-SNE is popularly used in high-parameter gene expression studies to understand the diversity of cell population and visualize the subpopulations in low-dimensional space. Recently this has emerged as a state-of-the-art method that has been adopted in other domains such as spatial zone delineation in geology and hydrology, biomedical signal

t-Distributed Stochastic Neighbor Embedding,

analysis, natural language processing, and music analysis. While t-SNE can be used for visual interpretation of the clusters presents in the high-dimensional data in the low dimension, the method cannot be used as a standalone method

for cluster extraction. Recent studies have proposed how this can be achieved as an ensemble approach by incorporating other machine learning techniques. Further studies are needed to optimize the t-SNE results.

Text Mining

Chengbin Wang¹ and Xiaogang Ma²

¹State Key Laboratory of Geological Processes and Mineral Resources & School of Earth Resources, China University of Geosciences, Wuhan, China

²Department of Computer Science, University of Idaho, Moscow, ID, USA

Definition

Text mining in geoscience is an emerging research area that uses methods of natural language processing and machine learning to extract structured information from the unstructured geoscience literature and makes semantic reasoning for knowledge discovery in geosciences. Research topics of text mining include, but are not limited to, text clustering, word segmentation, document summarization, entity and semantic relation extraction, knowledge base, and graph.

Text Mining and Mathematical Geosciences

Geoscience is a knowledge-intensive discipline. It contains large amounts of numeric spatial dataset (e.g., remote sensing, geochemistry, and geophysics) and map dataset. The rapid development of detection techniques in the micro- and macroscales in the past decades has been increasing both the

volume and quality of geoscience data. The mathematical geoscience is to apply mathematical methods and computers for processing these spatial geoscience data for knowledge discovery, such as mantle convection (Iwamori et al. 2010), mineral predication, discovery of new minerals (Morrison et al. 2017), geologic modeling, and lithofacies identification.

Moreover, the numeric dataset and map dataset are not the only outputs of geoscience research. Important information and knowledge produced by geoscience researches are recorded in unstructured textual form and thus hidden in the big data of geological literature (Wang and Ma 2019). Gil et al. (2018) proposed a research agenda of intelligent systems for geosciences that will result in fundamental new capabilities for understanding the Earth system. Automated information extraction and integration from published literature is listed as a key research direction in the agenda. In the era of big data, geoscience literature has become a big “mineral resource” for data mining. The improved computing performance including software and hardware enables an opportunity to understand the evolution of Earth system using text mining from geoscience literature (Wang and Ma 2019). The text mining for geoscience literature has become a new research direction and hotspot in the mathematical geosciences.

Text Mining for Geoscience Literature

Geoscience literature not only shares some common characteristics with other types of literature, but also is characterized by the spatial information and multidisciplinary terminology. Text mining for geoscience literature must depend on the geoscience knowledge. Therefore, building domain ontology and vocabulary of geosciences is a basic step for text mining. The ontology model determines which entities and semantic relationship information to extract from the geoscience literature. In the field of geoinformatics, a series of geological ontology models have been designed for different purpose, such as geologic time (Cox and Richard 2015; Ma et al. 2011, 2012; Wang et al. 2018a), geological modeling (Perrin et al. 2005), geological map (Mantovani et al. 2020), SWEET (Raskin 2006), mineral exploration (Ma et al. 2010), and geological structure (Zhong et al. 2009).

The first step of text mining is collecting and preprocessing text data. There are many forms for users to get the text data. For example, API permission from an online database, document scanning, and data extracting from Web. The obtained data from different sources may be recoded in diverse formats, such as text files and scanned images. It is necessary to transform the data into an organized, computer-readable format (Wang and Ma 2019). Due to the ambiguity, polysemy, and irregular input, it is difficult for computers to read and

understand the text data of natural language. Therefore, it is necessary to segment a piece of geological text into semantic word sequences for further computer processing (Wang and Ma 2019).

After geoscience literature data is structured, different topics including text clustering, document summarization, entity and semantic relation extraction, knowledge base, and graph can be studied. However, many geoscientists prefer to extract entities and their semantic links to build domain knowledge base and knowledge graph (Qi et al. 2020). Knowledge graph is a semantic network with directed graph structure. Each node in a graph represents an entity, and an edge represents the linking relationship between two entities (Wang et al. 2018b). The graph visualizes the nodes and the links between nodes to represent the information network and semantic relationships in a specific domain. The knowledge base is data pool to store knowledge graph in the form of triples. An informative geoscience knowledge base and knowledge graph can provide an infrastructure for geoscience scientists to change scientific research paradigm and be used to explore knowledge discovery for some big science questions such as origin of life and coevolution by the way of semantic reasoning.

Traditional statistical methods are unable to process geoscience literature. The information extraction from geoscience literature depends on the machine learning method. The machine learning methods of CNN (Convolutional Neural Networks), LSTM (Long short-term memory), and CRF (Conditional random field) have been applied in information extraction from geological literature (Qiu et al. 2018; Li et al. 2018; Wang et al. 2018b). The development in interpreted programming language and the wide-spreading open-source libraries enable scholars in various disciplines to quickly learn the latest algorithms and apply them to their domain-specific researches (Wang and Ma 2019). There are many widely used open and free libraries in text mining, such as TensorFlow (Abadi et al. 2016), DeepDive (De Sa et al. 2016), Caffe (Jia et al. 2014), CNTK (Seide and Agarwal, 2016), and MXnet (Chen et al. 2015). Even if a researcher has only the basic skills in programming, he or she will be able to make a good application of text mining using these libraries.

Text mining is still a new research direction in geoscience and has been used to assist to database construction and knowledge discovery. PaleoDeepDive, a machine reading system, was developed to extract fossil information from literature. The extracted results have been used to update the PBDB database (Peters et al. 2014). The GeoDeepDive, the updated version of PaleoDeepDive, is still ongoing and extracts geological unit information in North America from the geological literature and build the Macrostrata (<https://macrostrat.org/>).

Summary

Although text mining is an emerging research direction for geosciences, the research outputs have proven it is a powerful tool to transform earth science by providing new research tool, new data sources, and research views in the era of big data and artificial intelligence. This research direction requires the attention and involvement of more computer scientists and earth scientists.

Thickening

B. S. Daya Sagar¹ and D. Arun Kumar²

¹Systems Science and Informatics Unit, Indian Statistical Institute, Bangalore, Karnataka, India

²Department of Electronics and Communication Engineering and Center for Research and Innovation, KSRM College of Engineering, Kadapa, Andhra Pradesh, India

Definition

Thickening is a mathematical morphology (MM) based operation which is used to *expand/grow* selected regions of image. The MM-based operations such as dilation and closing are used to grow the selected regions in an image. The thickened images (TIs) are the images with enhanced regions and detailed information.

Introduction

Remote sensing images provide the spatial information related to the objects in an area of interest in the form of digital number (DNs) (Jensen 2004). The images consist of finite elements called pixels/pels or patterns. A pixel is associated with features. Each pixel is characterized by features (Richards and Jia 2006).

There exist various approaches to pre-process and process the digital images acquired from sensors (Campbell 1987). The basic approach is the application of mathematical/statistical models on the input images to implement the tasks such as image segmentation, image classification, and change detection (Lillesand and Kiefer 1994).

The remote sensing image analysis is implemented in important domains like spatial, frequency, and wavelets. In spatial domain, the kernel/window/filter is applied on the image to extract the shape/size information of the objects in area of interest. The important operations such as convolution, filtering, and structuring elements (SEs) are applied on input images in spatial domain.

The study related to the application of SE to extract the information from input image is discussed in mathematical morphology (MM). MM deals with the extraction of shape/size features of the objects in an image. MM is mathematically implemented using set theory (Matheron 1975).

There are various types of operations to extract the information content from images using MM. The operations are erosion, dilation, opening, closing, and hit-miss (Serra 1982). The operators such as erosion-dilation, opening-closing, thickening-thinning are dual operators. The detailed study of these operators is given in basic literature related to MM (Serra 1982). In the present study, a detailed discussion of thickening operation is given in the next section.

Thickening

The TIs are obtained by applying morphological operators with structuring element (SE). The SE is a morphological filter/kernel/window used to extract/enhance the information content in the input image (Soille 1999). In thickening, the SE is applied on the input image to obtain the enhanced images. The thickening operation on the input image using the SE (B) is given as:

$$\text{Thicken}(X, B) = (X) \cup (HM(X, B)), \quad (1)$$

where, X is an input image, B is structuring element (part of X). $HM(X, B)$ is hit and miss transform of B :

$$HM(X, B) = (X \ominus B_1) \cap (X^C \ominus B_2), \quad (2)$$

Thickening, Fig. 1 Input binary image with black background and white objects in foreground (Fisher et al. 1996)

Thickening, Fig. 2 Thickened image generated by applying thickening operator on input image (given in Fig. 1) (Fisher et al. 1996)

where B_1 and B_2 are SEs related to elements of B , associated with object and background, $\ominus$ is erosion operator, X^c denote the complement of image X , and X^c is generated by replacing 1 with 0 and vice versa at each pixel of X .

Thickening is the dual of thinning. Thinning is equivalent to thickening the foreground. Thickening operation is implemented in important applications like skeleton by zone of influence (SKIZ). SKIZ is the process of dividing the objects in the image into sub regions. SKIZ is similar to Voronoi diagrams that are used to get the zone of influences in an area of interest (Sagar 2013).

Example

In the present study, the morphological thickening is applied on input image shown in Fig. 1. The input image is binary image with black background and white foreground. The black background is represented with binary 0s, and the white foreground is represented with binary 1s. A morphological thickening operation is performed on input image to generate a thickened image as given in Fig. 2. In Fig. 2, the input image is thickened by 45° filter, and so the objects in Fig. 1 are closed as given Fig. 2.

Thickening increases the area of objects in the image. In real-time applications, thickening is applied to create the buffer zones to the themes like water, traffic, land water extent.

Application of Thickening in Remote Sensing Image Analysis

In the present study, the thickening of objects like vegetation, built-up land, water bodies, etc, is obtained by operating structuring element of size 5×5 on the input image acquired

Thickening, Fig. 3 (a) Input image – sentinel multispectral imager (MSI) of Mumbai City, India, and (b) thickened image obtained by operating a 5×5 structuring element on input image

from sentinel-multispectral imager (MSI). The input image and the thickened images are given in Fig. 3a and Fig. 3b respectively. The input image of Mumbai City, India, with three major classes, namely, water, vegetation, and built-up land, as shown in Fig. 3a. The classes such as water, vegetation, and built-up land are thickened to generate the buffer zones as shown in Fig. 3b. Furthermore, the classes in input image and thickened image are mapped into vector layers to generate thematic layers which can be used for various applications.

Conclusions

In the present study, the MM-based operation named as thickening is discussed with an example. Thickening is implemented to enhance the information content in input image by thinning the information content of background

and increasing the information content of object in foreground. Thickening provides the shape/size information of objects in an image. The real-time applications of thickening include creating river buffer, road buffer zones, etc.

Thiergärtner, Hannes

Heinz Burger

Geoscience, Free University Berlin, Berlin, Germany

Fig. 1 Hannes Thiergärtner, courtesy of Prof. Thiergärtner

Biography

Hannes Thiergärtner belongs to the few geoscientists who introduced the development and application of mathematical procedures within the German area. His domain is the testing, adoption and use of deterministic, stochastic and heuristic models in geological research required for the discovery of mineral deposits: the important subject of statistically based mineral resource estimation. Above all, the development of new geoscientific fields of application always were and still are the central issue of his work.

Hannes was born in Dessau (Germany) in 1938 and educated in petrography, geochemistry, mineral deposit geology, mathematical statistics and programming languages at the Mining Academy of Freiberg (former GDR) where he obtained his PhD for the statistical processing of geochemical data (1967) and postdoctoral habilitation for contributions to a system of computer-aided geological data processing (1971).

For two decades, Hannes tested numerous mathematical approaches applied to geoscientific subjects and processes as senior staff member in the Central Geological Survey Berlin. Proven algorithms and methods, for example, for multivariate profile correlation in deep drilling projects, lithological classification of East German geological units, and spatial modeling of geochemical data. Outline of quasi-homogenous areas for predictive results were applied by him to explore Atlantic deep-sea mud, Baltic Sea sand, and gravel, in order to support geochemical surface prospection or reserve estimation of mines. Later he extended the scope of his work to ecological problems. His methodological progress was communicated in dozens of lectures within the German Geological Society which acknowledged these pioneer activities by awarding him the Abraham-Gottlob-Werner-Medal. Hannes was also concerned with the development of a multilingual Geoinformation System and transnational exchange of geoscientific information in collaboration with the Council for Mutual Economic Assistance, where he represented the former GDR in its subsystem GEOINFORM. He was appointed a member of the regional group of European countries in the Commission COGEODATA of the International Union for Geological Sciences from 1987 to 1990 but because of political restrictions he could communicate only with scientists from Eastern Europe. (Before 1990 very few meetings with Western colleagues were possible – under more or less conspiratorial circumstances – during conferences held in Eastern Europe).

Following additional ecologic training, he became a leading evaluator of contaminated subsoil and groundwater in the Governmental Agency for the re-privatization of industrial

companies from 1990 to 2000. Later he worked in this field as a freelancer.

Hannes was university lecturer for mathematical geosciences at the Mining Academy Freiberg, the Greifswald University, and the Free University Berlin which appointed him as extraordinary professor in 1999. He published books on the statistical processing of geochemical data (Thiergärtner 1968) and the geology of his home town and surrounding areas (Thiergärtner 2011) as well as more than 100 contributions mainly covering the application of mathematical methods to geoscientific and ecological issues. Additionally, he acted as a guest editor for several issues of geoscientific journals, one with eight contributions by IAMG founding members (Zt. Deutsche Geologische Gesellschaft, Stuttgart 155(2–4):195–285, 2005). In 1996, he established the journal *Mathematische Geologie* published at CPress Publ. (Dresden) with international contributions. He edited this journal until 2003.

Hannes Thiergärtner belongs to the founding members of the International Association for Mathematical Geosciences at the International Geological Congress 1968 in Prague. He could reactivate his IAMG membership after the German Reunification in 1990 and subsequently contributed to numerous IAMG annual conferences.

Hannes is acknowledged as a humble and creative worker not made for public showmanship but for staying primarily a geoscientist. He is married and has two adult children. In 2013 he finished his sporting career as a long-distance rower after completing exactly the mathematically exact number of 55,555 training kilometers for which he obtained the Equator Award of the German Rowing Union.

Three-Dimensional Geologic Modeling

Qiyu Chen², Gang Liu^{1,2}, Xiaogang Ma³ and Junqiang Zhang²

¹State Key Laboratory of Biogeology and Environmental Geology, Wuhan, Hubei, China

²School of Computer Science, China University of Geosciences, Wuhan, Hubei, China

³Department of Computer Science, University of Idaho, Moscow, ID, USA

Definition

Three-dimensional geologic modeling (three-dimensional geomodeling) is the three-dimensional digital characterization, reconstruction, and reproduction of geological objects, phenomena, and processes through the comprehensive use of modern cutting-edge theory and technology, such as computer science, spatial information theory, scientific visualization technology, etc. From a broad sense, three-dimensional geomodeling is an integrated workflow of geological data and information processing including data organization and management, spatial information processing, geological interpretation, three-dimensional visualization, geological spatial analysis, statistical analysis, prediction, and so on. The purpose of three-dimensional geomodeling is to provide a visualization platform integrating scientific research, aided design, and decision support for geoscientists to deeply understand and utilize the essence and laws of geological bodies, phenomena, and processes. Building three-dimensional geological models from field and subsurface data has been a typical task in geological studies involving basic geological survey, natural resource evaluation, and hazard assessment.

Cutting-Edge Technologies of Three-dimensional Geologic Modeling

Three-dimensional geomodeling is about modeling the topology, the geometry, and the properties of a particular region (Mallet 2002). It has been rapidly developed in the past two decades through the promotion of powerful application requirements and the development of computer hardware/software, spatial information theory, three-dimensional visualization technology, and other related disciplines. The three-dimensional visualization of geological structures and heterogeneous properties can provide a more realistic and intuitive characterization of subsurface geological phenomena and

structures. Three-dimensional geological models are able to show the subsurface geological structures and physicochemical properties in a virtual three-dimensional space. Three-dimensional geomodeling has been a basic task in geological studies, geological survey, and engineering applications as well as the development of geological information system.

Three-dimensional geomodeling technology began in the 1980s (Houlding 1994), and has now formed a relatively mature modeling method system. It combines spatial information management, geological interpretation, spatial analysis, geostatistics, prediction, and visualization in a three-dimensional environment. The main contents of three-dimensional geomodeling include the study of three-dimensional spatial data model and the development of three-dimensional geomodeling methods. There are many methods for constructing three-dimensional geological models, which can be summarized as the methods for different data sets, data- and/or knowledge-driven methods, explicit and implicit methods, and geostatistics-based stochastic simulation methods. For different modeling objects, different data sources, or different uses of the models, the spatial data model and the geomodeling method are also different.

Object: Geological Structures and Properties

The objects of three-dimensional geomodeling include all subsurface structures and properties, such as geological structure, strata, rock type, various physicochemical properties, etc. For different objects, various three-dimensional geomodeling methods have been proposed, such as methods of modeling sedimentary stratigraphic framework, three-dimensional geomodeling methods of complex geological structures such as faults, folds, lenses and so on, and methods of modeling various physical and chemical properties, etc.

Data Sources

Three-dimensional geomodeling generally starts with spatial points, lines, or surfaces interpreted from geological observations, surveys, explorations, measurements, and analyses (Wellmann and Caumon 2018). The data used in geomodeling is very heterogeneous and includes all direct and indirect multiple-source data obtained during whole geological surveys and explorations. More precisely, three-

dimensional geomodeling applications typically use several data types:(1) different sources: data from different exploration departments, with different geological periods, and with different software formats; (2) different dimensions: one-dimensional observation points, two-dimensional geological maps/sections, three-dimensional DEM, etc.; (3) different types: remote sensing data, field observation data, drilling data, logging experiment data, artificial seismic data, gravity/magnetic data, physicochemical properties, etc.; (4) different precisions and scales, such as remote sensing data with different precisions, geological maps at different scales, etc. One of the goals of three-dimensional geomodeling is to continuously research and develop new technologies and methods, and use the above-mentioned data to perform three-dimensional visual characterization of subsurface geological structures and properties. So far, a series of three-dimensional geomodeling methods for different type data have been proposed, such as the automatic construction method of three-dimensional stratigraphic framework by using borehole data, the three-dimensional reconstruction method of regional geological structures through geological planes, and the interactive three-dimensional geomodeling method based on topological reasoning of geological sections, three-dimensional automatic reconstruction method by fusing multiple-source data (e.g., drilling data, remote sensing data, seismic data, and so on), etc. Therefore, how to effectively gather and use the above-mentioned multiple-source heterogeneous data to construct more reliable three-dimensional geological models is one of the most important challenges in this field.

Spatial Data Model

Three-dimensional geological modeling technology is accompanied by the development of spatial data model. As shown in Table 1, more than 20 data models have been developed (Wu 2004). They can be divided into surface-based models and voxels-based models. Generally, when modeling the spatial geometry of geological structures or geological objects, surface-based models will be used. However, voxel-based models are more advantageous for performing quantitative evaluation, analysis and prediction of geological resources, and dynamics simulation of

Three-Dimensional Geologic Modeling, Table 1 Categories of three-dimensional spatial data models (Wu 2004)

Surface-based model	Voxel-based model		Mixed model
	Regular volume	Irregular volume	
Irregular triangular network (TIN)	CSG-tree	Tetrahedral network (TEN)	TIN-CSG
Grid	Voxel	Pyramid	TIN-Octree
Boundary representation (B-Rep)	Octree	Tri-prism (TP)	Wire Framework-Block
Nonuniform rational B-splines (NURBS)	Needle	Geocellular	Octree-TEN
Wire-frame	Regular block	Irregular block	B-Rep-Voxel
Serial sections		Solid	
Sections-TIN mixed		Three-dimensional voronoi volume	
Multiple-DEMs		Generalized tri-prism (GTP)	

modeling. The formation and evolution of geological structures processes are extremely complex. It is difficult to approximate and characterize the reality only by limited data. The Both paths of the two viewpoints are linked in multiple ways, but share several commonalities. Geological knowledge is used in almost all steps such as data processing, conceptual and mathematical model construction, parameterization, and inversion. As a core step, fundamental principles and geological knowledge combine geological and geophysical information as well as conceptual and mathematical model in a principled way.

The data-driven approach may lead to the conflict between subsurface realizations and geological concepts or observations. Conversely, a common criticism for the geomodel-based approach is that (a) it starts with subjective information, which may induce bias in the model forecasts, (b) it contains interpretative elements that cannot be verified, and (c) it introduces a level of complexity that is not supported by data. Therefore, an integrated geomodeling viewpoint that fuses various data, models, and geological knowledge will be expected.

Explicit and Implicit Methods

Three-dimensional explicit modeling methods refer to determining the interfaces between different geological objects with three-dimensional surface meshes by using a human-machine interactive or semi-automatic way in a three-dimensional domain. Surface meshes consist of mainly triangular irregular networks (TINs) or parametric surfaces such as NURBS.

The surface mesh consists of a set of three-dimensional nodes, so the main task is to effectively organize these three-dimensional points through human-computer interaction or interpolation on the basis of sparse data extracted from such as boreholes, cross-sections, maps, etc. In order to obtain enough three-dimensional points to express geological interfaces, various implementation variants such as splines, inverse distance weight, kriging, and NURBS have been developed and utilized in this process. As all of these methods connect points by linear segments, they tend to create very angular geological surfaces. Smoothing methods such as discrete smooth interpolation (DSI) method (Mallet 1989) allow to obtain more realistic shapes while honoring subsurface data. Although it is easy to integrate expert experience into three-dimensional geological models, it also brings uncertainty that cannot be assessed. Model construction can be automated in relatively simple structural cases, but their application in complex domains generally involves significant manual editing. For complex geological structures, the limitations of the low efficiency have gradually become prominent. Once the modeling data changes or new data is obtained, the modeler needs to reinterpret the data and rebuild the models, which causes great difficulty in model updating.

Implicit methods are more recent and they have opened new ways to automatically construct geological models with a high degree of complexity. The idea of implicit methods is to compute the scalar field $s(x)$ so that all data points sampling the surface have the same scalar value (Mallet 2002). Two main numerical methods have been proposed to create individual implicit surfaces from sparse data points: meshless methods and mesh-based methods. The general form of meshless methods includes radial basis function (RBF) interpolation and dual kriging. These meshless methods are very convenient but they involve solving a large and dense linear system. Mesh-based methods have also been proposed to compute the scalar field (Caumon et al. 2009). In this case, the domain is covered by a linear tetrahedral mesh conformable to discontinuities. Implicit methods directly consider volumes and are overall more robust and automatic than surface-based models. Complex geological structures can be obtained automatically without need for expert input and user interaction. Another capability of implicit methods is to honor several types of structural data without any projection. In terms of model updating, implicit methods also showed a significant advantage due to the automation of interpolation used in them (Wellmann and Caumon 2018).

Geostatistics-Based three-dimensional Simulation and Modeling

Geostatistical simulation is one of the most important tools for building an ensemble of probable realizations in earth science (Journel and Huijbregts 1978). Three-dimensional characterization and modeling of geological structures have been investigated for several years via geostatistical simulation. Several simulation methods have been proposed that can produce various realizations. Methods such as sequential Gaussian simulation (SGSIM) and sequential indicator simulation (SISIM) have become popular among different fields of earth sciences. These methods give a number of realizations or interpolation scenarios, which allow assessing the uncertainty and quantifying it more accurately. Due to relying on variogram, kriging-based geostatistical simulations are not able to reproduce complex patterns. Clearly, considering only two points is not sufficient for reproducing complex and heterogeneous models. Thus, several attempts in the recent years in the context of multiple-point geostatistics (MPS) have been made (Mariethoz and Caers 2014) that can capture high-order (more than two points) statistics simultaneously from a reference model called training image (TI). MPS-based simulation has recently gone under a remarkable progress in handling complex and more realistic phenomenon that can produce large amount of the expected uncertainty and variability. Several three-dimensional applications have demonstrated its applicability in three-dimensional characterization and modeling of complex geological structures (Mariethoz and Caers 2014).

Three-Dimensional Geologic Modeling, Fig. 2 Three-dimensional geological structure-property integrated modeling framework based on geostatistical simulation (Chen et al. 2020)

Because geostatistics-based simulations are usually performed on a regular Cartesian grid, the realizations cannot realistically reflect the exact morphology features of geological structures. In addition, geostatistical simulation should be done under the constraints of fundamental principles and geological knowledge. Therefore, it is an effective way to develop a three-dimensional structure-property integrated modeling method based on geostatistical simulation under

the constraints of surface-based models. Figure 2 shows a three-dimensional stochastic modeling framework for complex subsurface structures and properties by using conditional simulation technique (Chen et al. 2020). Under the framework, the realizations and various properties can be integrated into a unified model grid resulting in integrated management and analysis of these multiple three-dimensional models in a unified three-dimensional space.

Conclusions and Outlook

The fundamental goal for the theory of geological modeling is to obtain methods that allow a reasonable description of geometric features and physicochemical properties in full three-dimensional space. Geological modeling methods have been rapidly developing over the last years. Various heterogeneous data have been used to construct three-dimensional geological models. A series of three-dimensional geomodeling methods for different type data have been proposed. Arguably, two different viewpoints, data-driven and geomodel-driven, are both complementary of each other to promote the development of three-dimensional geomodeling methods, and act on every step of the three-dimensional geomodeling process. They are curly divided into explicit and implicit methods. They have their own characteristics and have been applied in various application fields of three-dimensional geomodeling. However, implicit methods are more recent and they allow to automatically construct complex geological models. Geostatistical simulation is able to automatically reproduce a number of realizations, and their ability for characterizing and modeling geological structures in three-dimensional domain have also been investigated. In the end, several interesting perspectives and recommendations for future research in the field are outlined as follows.

- **Integration:** In addition to integrating various types of heterogeneous data, geological knowledge, and mathematical models into three-dimensional geological models, the integrated characterization of geological structures and properties is still a challenge. Therefore, new unified spatial data models and integrated modeling methods are expected. In addition, the integrated expression, scheduling, and management of three-dimensional models with different scales is also a problem. In the big data era, three-dimensional geological models should be given more functions and capabilities. Three-dimensional geological models are not only used to the present subsurface geological structures and properties, but also are the platforms and portals of the integration, management, mining, visual analysis, and sharing of geological big data.
- **Visualization:** In order to further enhance the visual effect and reality of three-dimensional geological models, new visualization technologies such as virtual reality (VR) and augmented reality (AR) should be used in three-dimensional geomodeling. Moreover, advanced scientific visualization and visual analysis technologies can help data mining and knowledge discovery from three-dimensional geological models.
- **Efficiency:** In practice, the computational efficiency of modeling and simulation methods remains limited with regard to the ambition of creating reasonably accurate models explaining all observations. The development of

efficient exploiting modern parallel computer architectures is an essential area for future advances.

- **Machine learning:** The advent of efficient machine learning methods opens very interesting perspectives in the field of joint geological modeling and geostatistical simulation. Many effective approaches have been used to improve the automation and intelligence of three-dimensional geomodeling, and their effectiveness has been investigated. It shows great potential in the field of three-dimensional geomodeling in the future.

Definition

Some of the interesting geoscience applications to the time series (TS) users can be understood by data extracted from daily mean values of solar radiation obtained at the Earth's surface (Gilgen 2006), earthquake and explosion occurrences (Shumway and Stoffer 2011), intensity returns from synthetic aperture radar imagery (Almeida-Junior and Nascimento 2021), among others. The main goals of the time series analysis (TSA) are to propose mathematical models to describe the dependence structure of real phenomena and to predict the associated future values.

A time series can be understood as a collection of random variables with time-ordered indices a subset $\mathcal{T}$ of $\mathbb{Z}$ or $\mathbb{R}$. Mathematically, the sequence $\{X_t; t \in \mathcal{T}\}$ is a stochastic process (SP). The observed values of a SP are called the outcomes of the respective SP. In this chapter, it will adopt $t \in \mathcal{T} \subset \mathbb{Z}$. From now on, the term time series will refer to both the SP and one of its particular realizations.

The remainder of this chapter is outlined as follows. First, the TSA main concepts are presented. Second, it is approached a smoothing process by the state-space model (SSM). Third, the seasonal autoregressive integrated moving average (SARIMA) model is discussed. Finally, to illustrate the presented concepts, an application is made to time series of vegetation indices obtained with the Moderate Resolution Imaging Spectroradiometer (MODIS). All computational operations are made using the software R, cf. Shumway and Stoffer (2011), Appendix R. In particular the package `dtwSat` (Maus et al. 2019) is used for extracting the data and `forecast`, `seastests`, and `fpp` for doing the statistical operations with time series.

This chapter is intended to provide the reader with knowledge of the TSA. Basic courses in statistics and calculus theories are assumed as prerequisites.

Initial Concepts

The Time Domain Approach and Stationarity

Let $\{X_t; t \in \mathbb{Z}\}$ be a time series. X_t is said to be stationary (also known as weak stationarity, covariance stationarity, stationarity in the wide sense or second-order stationarity), if

- (i) $E|X_t|^2 < \infty$, for all $t \in \mathbb{Z}$;
- (ii) $EX_t = m$, for all $t \in \mathbb{Z}$;
- (iii) $\gamma_X(r, s) = \gamma_X(t + r, t + s)$, for all $r, s, t \in \mathbb{Z}$,

where $E(\cdot)$ is the expected value, $\text{Cov}(\cdot, \cdot)$ is the covariance operator, and $\gamma_X(r, s) \triangleq \text{Cov}(X_r, X_s)$. If $\{X_t; t \in \mathbb{Z}\}$ is a stationary time series, $\gamma_X(r, s) = \gamma_X(r - s, 0)$ for all $r, s \in \mathbb{Z}$. Thus, the autocovariance function (acvf) of a stationary process is defined as the function of one variable:

$$\gamma_X(h) \triangleq \gamma_X(h, 0) = \text{Cov}(X_{t+h}, X_t), \text{ for all } t, h \in \mathbb{Z}.$$

The term “ $\gamma_X(h)$ ” indicates an acvf of X_t at the lag h . The acvf satisfies the properties:

$$(i) \gamma_X(0) \geq 0; (ii) |\gamma_X(h)| \leq \gamma_X(0) \text{ for all } h \in \mathbb{Z},$$

$$\text{and } (iii) \gamma_X(h) = \gamma_X(-h),$$

i.e., it is limited and even. Other important function defined from $\gamma_X(h)$ is the autocorrelation function (acf) of $\{X_t\}$, say $\rho_X(h)$, defined as:

$$\rho_X(h) \triangleq \text{Cor}(X_{t+h}, X_t) = \frac{\text{Cov}(X_{t+h}, X_t)}{\sqrt{\text{Var}(X_{t+h})\text{Var}(X_t)}} = \frac{\gamma_X(h)}{\gamma_X(0)},$$

for all $t, h \in \mathbb{Z}$, where $\gamma_X(0) = \text{Var}(X_t)$ and $\text{Cor}(X_{t+h}, X_t)$ is the correlation operator between the variables X_t and X_{t+h} . For $h \in \mathbb{Z}$, the acf $\rho_X(h)$ satisfies the properties:

$$(i) \rho_X(0) = 1, (ii) |\rho_X(h)| \leq 1, \text{ and } (iii) \rho_X(h) = \rho_X(-h).$$

Other important measure is the partial acf (pacf) that can be defined in terms of $\rho_X(h)$ as

$$\pi_X(h) \triangleq \frac{\rho_X(h) - \alpha_1 \rho_X(h-1) - \dots - \alpha_{h-1} \rho_X(1)}{1 - \alpha_1 \rho_X(1) - \dots - \alpha_{h-1} \rho_X(h-1)},$$

where α_i , for $i = 1, \dots, h-1$, are obtained by determinant relations involving $\rho_X(h)$ (Wei 2006, p. 13).

Introducing an Example in Geoscience

To illustrate some of the concepts discussed, consider the introduction of the application context used in this chapter. Remote sensing using imagery data is one of the most commonly used methods for measuring changes in land use and land cover. The time series to be modeled refers to the Enhanced Vegetation Index (EVI) obtained from a series of MODIS MOD13Q1 (Didan 2015) images acquired from 2009-08-05 to 2013-07-31 with ninety-three observations. Figure 1a shows the EVI series fluctuating around the mean value 0.4221. Figure 1b shows the corresponding samples acf and pacf, which indicate an expressive dependence structure possibly indicative of a third-order autoregressive pattern, suggesting the cut after the third lag in the sample pacf. Some descriptive measures of the observed time series are given in Table 1 (for abbreviations Coefficient of variation (CV), Standard Deviate (SD), Minimum (Min.), and Maximum (Max.)).

It follows that EVI values vary in the range (0.0809, 0.9227), the differences between pairs (Min., 1° Quartile),

Time Series Analysis,**Fig. 1** EVI observed series and its sample acf and pacf

(a) EVI observed series

(b) The sample acf and pacf

Table 1

Min.	1st Quartile	Median	Mean	SD	CV	3rd Quartile	Max.
0.0809	0.1924	0.3227	0.4221	0.2619	62.0498%	0.6455	0.9227

(Median, Average), and (3° Quartile, Max.) are expressive, and the CV indicates a meaningful dispersion. In what follows, two modeling strategies are presented.

Smoothing Methods

Hyndman et al. (2008) have presented an important class that includes various smoothing models. Let $\{X_t\}$ be a time series and $\{y_t\}$ a vector of unobserved components (called states) to describe trend (level and inclination) and seasonal effects in X_t . Then the SSM is given by

$$\begin{cases} X_t = \mathbf{w}^\top \mathbf{y}_{t-1} + Z_t \in \mathbb{R} \text{ [Relation between } (X_t) \text{ and states } (\mathbf{y}_t)], \\ \mathbf{y}_t = \mathbf{F} \mathbf{y}_{t-1} + \mathbf{g} Z_t \in \mathbb{R}^p \text{ [transition equations]}, \end{cases} \quad (1)$$

where p represents the number of transition equations, $\{Z_t\}$ represents the Gaussian white noise (GWN) having $\mathbf{E}(Z_t) = 0$ and $\text{Var}(Z_t) = \sigma^2$, and $\mathbf{F}$, $\mathbf{g}$, and $\mathbf{w}$ are the associated coefficients. The nonlinear version for Eq. (1) is given by

$$\begin{cases} X_t = w(\mathbf{y}_{t-1}) + r(\mathbf{y}_{t-1})Z_t \in \mathbb{R}, \\ \mathbf{y}_t = f(\mathbf{y}_{t-1}) + g(\mathbf{y}_{t-1})Z_t \in \mathbb{R}^p, \end{cases} \quad (2)$$

where $w(\cdot)$ and $r(\cdot)$ are real-valued function and $f(\cdot)$ and $g(\cdot)$ are vector functions.

Hyndman et al. (2008) coined the notation (E, T, S) = (Error, Trend, Seasonality) for the SSMs. Some well-known smoothing models are particular cases in the ETS class. For instance, assuming the structures Additive “A,” Multiplicative “M,” and None “N,” (A, N, N) represents the simple exponential smoothing, (A, A, N) indicates the Holts linear model, (A, A, A) provides the Holt-Winters’ additive method, and (A, A, M) yields the Holt-Winters multiplicative model.

In practice, the initial states, say $\mathbf{y}_0$, and vector of parameters, $\boldsymbol{\theta}$, involved in models of Eqs. (1) and (2) are unknown and, therefore, should be estimated. According to Hyndman et al. (2008), the maximum likelihood estimators for $\boldsymbol{\theta}$ and $\mathbf{y}_0$ are obtained by minimizing the expression: Given a time series $X_1, \dots, X_n$ following Eq. (2),

$$S(\boldsymbol{\theta}, \mathbf{y}_0) = \left| \prod_{t=1}^n r(\mathbf{y}_{t-1}) \right|^{2/n} \sum_{t=1}^n Z_t^2$$

which is known as the augmented sum of squared errors criterion.

First Application

Now, consider the ETS model to describe the EVI series, discussed previously. We aim to model the first 88 observations and after to predict the five latter. By applying function `ets(.)` of the package `fpp` of the software R, the ETS (A, N, N) model was chosen:

$$\begin{cases} X_t = \ell_{t-1} + Z_t, \\ \ell_t = \ell_{t-1} + \alpha Z_t, \Leftrightarrow \ell_t = \alpha y_t + (1 - \alpha)\ell_{t-1} \\ \hat{X}_{t+h|t} = \ell_{t-1} \Leftrightarrow \hat{X}_{t+h|t} = \ell_t, \end{cases} \quad (3)$$

having the estimated smooth parameter $\alpha = 0.9999$, initial stage $\ell_0 = 0.1684$, and estimated standard deviate of Z_t $\sigma = 0.1684$, where $\hat{X}_{t+h|t}$ is the forecast equation in a horizon h . The fitted model suggested $\hat{X}_{88+h|t} = 0.5342041$ to predict the elements in (Table 2):

This fitted model presents the best forecast for $h = 1$. Figure 2 presents the ETS fit to EVI observed series. By visual inspection, it is noticeable that the acceptable fit. Applying the Ljung-Box test (in language R, by using `Box.test(., type = “Ljung-Box”)`), there is evidence at the nominal level of 1% that the associated residuals follow the GWN pattern.

The SARIMA Process

Definition and Some Particular Cases

Let X_t be a time series, $B\{X_t\} = X_{t-1}$ the backshift operator, and $B^s\{X_t\} = X_{t-s}$ its extension at the presence of a seasonal pattern with frequency s . Thus, the following polynomials can be defined: For $p, P, Q, Q_s, D, D_s \in \mathbb{Z}_+$,

$$\begin{aligned} \phi_p(B) &= 1 - \phi_1 B - \phi_2 B^2 - \dots - \phi_p B^p, \\ \theta_q(B) &= 1 + \theta_1 B + \theta_2 B^2 + \dots + \theta_q B^q, \\ \Phi_P(B^s) &= 1 - \Phi_1 B^s - \Phi_2 B^{2s} - \dots - \Phi_P B^{Ps}, \\ \Theta_Q(B^s) &= 1 + \Theta_1 B^s + \Theta_2 B^{2s} + \dots + \Theta_Q B^{Qs}, \\ \nabla^d &= (1 - B)^d, \end{aligned}$$

and

$$\nabla_s^{D_s} = (1 - B^s)^{D_s}.$$

Time Series Analysis,

Fig. 2 EVI observed and fitted series by the ETS model (observed series – solid black, predicted series – solid red, forecast lower and upper limits – dashed red, forecast – dashed blue)

**Time Series Analysis,**

Fig. 3 Class of SARIMA submodels

The SARIMA model is given as follows (Brockwell and Davis 1991): Let X_t be a process of mean zero (without loss of generality),

$$\Phi_P(B^s) \phi_p(B) \{\nabla_s^D \nabla^d X_t\} = \Theta_Q(B^s) \theta_q(B) Z_t$$

or, equivalently,

$$\Phi_P(B^s) \phi_p(B) Y_t = \Theta_Q(B^s) \theta_q(B) Z_t, \quad (4)$$

where $Y_t = \nabla_s^D \nabla^d \{X_t\}$ points out an application of operations to deal with the nonstationarity of X_t from nonseasonal (∇^d) and seasonal (∇_s^D) perspectives, d and D mean the non-seasonal and seasonal orders of differencing, $\phi_p(\cdot)$ and $\Phi_P(\cdot)$ represent the nonseasonal and seasonal autoregressive (AR) operators with orders p and P , $\theta_q(\cdot)$ and $\Theta_Q(\cdot)$ indicate the nonseasonal and seasonal moving average (MA) operators with orders q and Q , and Z_t follows a GWN. This model is denoted as $\text{ARIMA}(p, d, \varrho) \times (P, D, Q)_s$.

Figure 3 exhibits the main submodels in the SARIMA class. These submodels are resulting of the intersection between the stationary and seasonality characteristics:

- $\text{ARMA}(p, q)$ (stationarity and nonseasonality): $\phi_p(B) X_t = \theta_q(B) Z_t$ and $Z_t \sim \text{GWN}(0, \sigma^2)$.
- $\text{SARMA}(P, Q)_s$ (stationarity and seasonality): $\Phi_P(B^s) X_t = \Theta_Q(B^s) Z_t$ and $Z_t \sim \text{GWN}(0, \sigma^2)$.
- $\text{ARIMA}(p, d, q)$ (nonstationarity and nonseasonality): $\phi_p(B) \{\nabla^d X_t\} = \theta_q(B) Z_t$ and $Z_t \sim \text{GWN}(0, \sigma^2)$.
- $\text{ARIMA}(p, d, q) \times (P, D, Q)_s$ (nonstationarity and seasonality): $\Phi_P(B) \phi_p(B) \{\nabla_s^D \nabla^d X_t\} = \theta_q(B) \Theta_Q(B) Z_t$ and $Z_t \sim \text{GWN}(0, \sigma^2)$.

In practice, users of the SARIMA class need to identify from observed time series if there are (not) evidence for rejecting stationarity and seasonality, what is made by using hypotheses tests (Shumway and Stoffer 2011).

Estimation

To determine the estimation for the SARIMA parameters, consider the ARMA process defined from Eq. (4), taking $d = D = 0$ and $\Phi_P(B^s) = \Theta_Q(B^s) = 1$: Let $\{X_t; t \in \mathbb{Z}\}$ be a stationary process following the ARMA(p, q) process and $x_1, x_2, \dots, x_n$ be one of its n -points outcome with mean zero, then the associated joint likelihood is expressed as

$$L(\boldsymbol{\beta}, \sigma^2) \triangleq L(\boldsymbol{\beta}, \sigma^2; x_1, x_2, \dots, x_n) \\ = f(x_1, x_2, \dots, x_n; \boldsymbol{\beta}, \sigma^2), \quad (5)$$

where $f(\cdot)$ is the joint density of the process, $\boldsymbol{\beta}^\top = (\phi^\top, \theta^\top)$, $\phi = (\phi_1, \dots, \phi_p)^\top$, and $\theta = (\theta_1, \dots, \theta_q)^\top$. Now, consider a brief discussion on the likelihood-based estimation for $(\boldsymbol{\beta}^\top, \sigma^2)$. According to Hamilton (1994, ch. 5) and Brockwell and Davis (1991, ch. 8), the Gaussian closed-form likelihood can be derived from the factored density

$$f(x_1, \dots, x_n; \boldsymbol{\beta}, \sigma^2) = f(x_1; \boldsymbol{\beta}, \sigma^2) \times \prod_{t=2}^n f(x_t | x_{t-1}, \dots, x_1; \boldsymbol{\beta}, \sigma^2) \\ = (2\pi\sigma^2)^{-n/2} [r_1^0(\boldsymbol{\beta}) \times r_2^1(\boldsymbol{\beta}) \times \dots \times r_n^{n-1}(\boldsymbol{\beta})]^{-1/2} \exp\left[-\frac{S(\boldsymbol{\beta})}{2\sigma^2}\right],$$

where $S(\boldsymbol{\beta}) \triangleq \sum_{t=1}^n \left[\frac{(x_t - x_t^{t-1}(\boldsymbol{\beta}))^2}{r_t^{t-1}(\boldsymbol{\beta})} \right]$, $x_t^{t-1}(\boldsymbol{\beta}) \triangleq \mathbb{E}(X_t | X_{t-1} = x_{t-1}, \dots, X_1 = x_1)$ is the conditional mean of the Gaussian SP (GSP), and $r_t^{t-1}(\boldsymbol{\beta})$ is such that the conditional GSP variance is

$\text{Var}(X_t | X_{t-1} = x_{t-1}, \dots, X_1 = x_1) = \sigma^2 r_t^{t-1}(\boldsymbol{\beta})$. Thus, the maximum likelihood estimates are given by (Brockwell and Davis 1991)

$$\hat{\boldsymbol{\beta}} = \arg \max_{\boldsymbol{\beta} \in \mathbb{R}^{p+q}} \left[\log f\left(x_1, \dots, x_n; \boldsymbol{\beta}, \frac{1}{n} S(\boldsymbol{\beta})\right) \right]$$

Finally, this idea is easily applied for Eq. (4). Given values p, d, q, P, D, Q , note that $Y_t = \nabla^d \nabla^D X_t$ follows an ARMA($p + sP, q + sQ$) process and, thus, the $(p + P + q + Q)$ -dimensional parameter vector can be estimated by the previous process.

Second Application

Now, consider the SARIMA model to describe the first 88 observations of the EVI series and then predict the five latter. By applying function `auto.arima(.)` of the package forecast of the software R, the SARIMA model was chosen: As indicated by the interpretation of the sample pacf in Fig. 1b, an AR(3) model was fitted such that

$$X_t = 0.4312 + 0.9076(X_{t-1} - 0.4312) - 0.1443(X_{t-2} - 0.4312) \\ - 0.2614(X_{t-3} - 0.4312) + Z_t,$$

where the estimated variance of Z_t is $\hat{\sigma}^2 = 0.02614$. Using the function `predict(., n.ahead = 5)` of the package

Table 3

Time	2013-05-26	2013-06-13	2013-06-29	2013-07-15	2013-07-31
X_t	0.5434	0.4156	0.1220	0.1163	0.1309
$\hat{X}_{88+h t}$	0.4411681	0.3877664	0.3634413	0.3733872	0.3998829

Time Series Analysis,

Fig. 4 EVI observed and fitted series by the SARIMA model (observed series – solid black, predicted series – solid red, forecast lower and upper limits – dashed red, forecast – dashed blue)

forecast, the fitted model provides the forecast values in (Table 3):

This fitted model presents the best forecast for $h = 2$. Figure 4 presents the AR(3) fit to EVI observed series. By visual inspection, one can observe an acceptable fit. Applying the Ljung-Box test (`Box.test(., type = "Ljung-Box")`), there is evidence at any nominal level smaller than 92.92% that the associated residuals follow the GWN pattern.

Conclusion

In this chapter, we have presented the main concepts for understanding the time series analysis (TSA). Two specific models were discussed and applied to a time series of enhanced vegetation indices extracted from remote sensing radar.

Time Series Analysis in the Geosciences

Klaus Nordhausen

Department of Mathematics and Statistics, University of Jyväskylä, Jyväskylä, Finland

Definition

A time series is a collection of data taken sequentially over time and has therefore a natural one-way order where it can be assumed that the current value is more influenced by the

recent past than by observations from a long time ago. Time series analysis comprises methods for the analysis of time series which take this structure into account when extracting meaningful statistics from the data. Time series forecasting concerns the prediction of future values based on an observed time series.

Time Series Data

In geosciences, collecting data that depend on time have been measured for centuries. For example, temperatures have been observed in standardized ways since approximately 1860. But also recordings of river discharge have a long tradition. Records of such phenomena varying irregularly in time and when sequentially observed are called time series. If the measurements are recorded continuously, like from a seismograph, the time series is called continuous time series. On the other hand, if the measurements are taken at certain, usually regular, intervals like hourly, daily, monthly, or yearly, they are denoted discrete time series. Discrete time series with equally spaced intervals are the most common form of time series data and also the focus of this entry.

At a given time point t , it is possible to observe a single observation like temperature; a vector of observations like temperature, precipitation, and wind speed; or a curve like the temperature curve at day t . Then one distinguishes between univariate, multivariate, and functional time series, respectively.

However, independent of the type of time series, the irregularly varying nature of the recordings is addressed by assuming the observed time series is a realization of a stochastic model. And the most convenient assumption is that the stochastic model has some time-invariant structures in which case it is called stationary. If however the stochastic model itself depends on time, it is called nonstationary. The last differentiation between types of time series made here is between linear and nonlinear time series. If the stochastic model can be expressed as the output of a linear model, it is called a linear time series and if not, a nonlinear time series.

Objectives of Time Series Analysis

Time series analysis has three main objectives:

1. **Description:** Methods that describe or summarize characteristics of the time series. Thus this contains tools for visualization or appropriate summary statistics which help to capture the essential features of the time series.
2. **Modeling:** To represent the stochastic nature of the observed time series, many different models have been suggested which help understanding the nature of the

process. An adequate model needs to be selected and its parameters need to be estimated. The choice of a model is often based on the descriptive measures.

3. **Prediction:** Due to the serial nature of the time series, future values can be predicted based on the past and present values. To predict the future, it is important to have a model which represents the data well.

Descriptive Tools for Time Series

The first step of all time series analysis is its visualization. A typical time series plot is given in Fig. 1 which gives the monthly average temperatures in centigrade (C) at the airport of Jyväskylä in central Finland from 1960 to 2005.

Usually in such a figure for a time series $x_t, t = 1, \dots, T$ one evaluates if the mean over time has a tendency, which is usually denoted as trend m_t and if there are regularly appearing patterns known as seasonalities s_t . If both are present, one can consider an additive decomposition of the time series

$$x_t = m_t + s_t + r_t, \quad t = 1, \dots, T,$$

where r_t represents the stochastic feature of data.

To obtain an idea of the trend, usually moving averages of order n are used, which are defined as

$$m_t^n = \frac{1}{n} \sum_{j=t-k}^{t+k} x_j,$$

where $n = 2k + 1$. The larger the n , the smoother the trend estimate will be.

The seasonal component is assumed to reoccur regularly. For example, for our monthly temperature data from Fig. 1, visual inspection indicates no trend, but the values every $l = 12$ months appear to be similar.

To obtain an estimate for a seasonal component of length l , one usually estimates first the trend with $n = l$ if l is odd like for weekly data or $n = 2l$ if n is even as for monthly data. The estimate of the monthly effect is then the average of each

month of the detrended series standardized so that their sum is zero.

The random reminder is then simply $r_t = x_t - m_t - s_t$.

For simplicity, we consider for now the observed time series x_t as a realization of a stochastic process $X_t, t = 0, \pm 1, \dots, \pm \infty$ without a trend or seasonal component, like the reminder r_t from above. The mean value function of X_t is $\mu_t = E(X_t)$ and the autocovariance function at times t and $t - \tau$ is defined as $Cov(X_t, X_{t-\tau}) = E((X_t - \mu_t)(X_{t-\tau} - \mu_{t-\tau}))$. For $\tau = 0$, this reduces to the variance at time t . Thus the serial dependence of time series data is captured especially in the autocovariance function. However, when all these characteristics depend on t , they are not very tractable and therefore a common practical assumption is that

$$E(X_t) = E(X_{t+\tau}) = \mu, \quad Var(X_t) = Var(X_{t+\tau}) = \sigma^2$$

and

$$Cov(X_t, X_{t-\tau}) = Cov(X_{t-l}, X_{t-l-\tau}) = C_\tau,$$

for all τ and all l . Thus the mean and variance do not depend on the time, and the autocovariance depends only on the distance between the observations. Such a time series is called (weakly) stationary. For an observed univariate time series $x_t, t = 1, \dots, T$ then summary statistics to describe these time series features are under the stationarity assumption:

Empirical mean: $\hat{\mu} = \frac{1}{T} \sum_{i=1}^T x_i$,

Empirical variance: $\hat{\sigma}^2 = \frac{1}{T} \sum_{i=1}^T (x_i - \hat{\mu})^2$ and

Empirical autocovariance: $\hat{C}_\tau = \frac{1}{T} \sum_{i=\tau+1}^T (x_i - \hat{\mu})(x_{i-\tau} - \hat{\mu})$.

In addition, also the empirical autocorrelation $\hat{\gamma}_\tau = \hat{C}_\tau / \hat{\sigma}^2$ is often considered.

When the analysis of the time series is based mainly on the autocorrelation structure, one says one does the analysis in the time domain. Another approach is to analyze the data in the frequency domain. Then by employing spectral analysis, the time series is decomposed into trigonometric functions at each frequency, and its features are represented with the weights given to the periodic components.

Time Series Analysis in the

Geosciences, Fig. 1 Average monthly temperature at the airport in Jyväskylä in C from 1960 to 2005

If the autocovariance function C_τ rapidly decreases with increasing lag τ and satisfies

$$\sum_{\tau=-\infty}^{\tau=\infty} |C_\tau| < \infty,$$

one can define the Fourier transform of C_τ . For frequencies $-0.5 \leq w \leq 0.5$, the power spectral density function is then

$$p(w) = \sum_{\tau=-\infty}^{\tau=\infty} C_\tau e^{-2\pi i \tau w}.$$

For an observed time series $x_1, \dots, x_T$ one uses then the natural frequencies $w_j = j/T, j = 0, \dots, \lfloor N/2 \rfloor$ to obtain the periodogram

$$p_j = \sum_{\tau=-T+1}^{T-1} \hat{C}_\tau e^{-2\pi i \tau w_j} = \hat{C}_0 + 2 \sum_{\tau=1}^{T-1} \hat{C}_\tau \cos(2\pi \tau w_j),$$

which can be used to obtain the sample spectrum

$$\hat{p}(w) = \sum_{\tau=-T+1}^{T-1} \hat{C}_\tau e^{-2\pi i \tau w_j}$$

by extending the domain to the continuous interval $[0, 0.5]$. Thus, there is a direct relation between the sample spectrum and the sample autocovariance

$$\hat{C}_\tau = \int_{-0.5}^{0.5} \hat{p}(w) e^{2\pi i \tau w} dw, \quad \tau = 0, \dots, T-1.$$

Notice that in practice, the periodogram is usually computed with the fast Fourier transform (FFT), and in the time domain, plots of the autocorrelation function are often inspected while in the frequency domain, the periodogram is considered. Which approach is preferable often depends on the concrete application. For more details on these topics, see, for example, Gilge (2006), Kitagawa (2010), and Shumway and Stoffer (2017).

Time Series Modeling

Exploring the autocorrelation structure and/or the periodogram of a time series provides the starting point for modeling.

A highly popular class of time series models are autoregressive moving average (ARMA) models. For this purpose, we define first a white noise process. A process ε_t is called white noise process if $E(\varepsilon_t) = 0$, $\text{Var}(\varepsilon_t) = \sigma^2$ and $\text{Cov}(\varepsilon_t, \varepsilon_{t-\tau}) = 0$ for all t and all $\tau > 0$. Thus a white noise process is centered with constant variance and serially uncorrelated. In the following, we will also assume that ε_t is Gaussian.

An ARMA model expresses then a time series x_t as a linear combination of its past values x_{t-i} and a white noise process ε_t :

$$x_t = \sum_{i=1}^p \alpha_i x_{t-i} + \varepsilon_t - \sum_{i=1}^q \beta_i \varepsilon_{t-i}.$$

In this model, p is the autoregressive order with autoregressive coefficients $\alpha_1, \dots, \alpha_p$ while q is the moving average order with moving average coefficients $\beta_1, \dots, \beta_q$. A time series x_t which follows an ARMA model is called an ARMA process and is usually denoted ARMA(p, q). The special case ARMA($p, 0$) is called simply an autoregressive process AR(p) and ARMA($0, q$) a moving average process MA(q). It is meanwhile well established that almost all stationary time series can be modeled using autoregressive processes.

Interesting is also that, under certain conditions, all ARMA(p, q) models can be expressed as MA(∞) models, i.e., as linear combinations of present and past realizations of a white noise series

$$x_t = \sum_{i=0}^{\infty} \phi_i \varepsilon_{t-i}.$$

The coefficients ϕ_i in this representation are called the impulse response function and are given by the recursive expression

$$\phi_0 = 1 \quad \text{and} \quad \phi_i = \sum_{j=1}^i \alpha_j \phi_{i-j} - \beta_i, \quad i = 1, 2, \dots,$$

where $\alpha_j = 0$ for $j > p$ and $\beta_j = 0$ for $j > q$.

The impulse response functions can then be used to express the autocovariance function of an ARMA(p, q) model

$$C_0 = \sum_{i=1}^p \alpha_i C_i + \sigma^2 \left(1 - \sum_{i=1}^q \beta_i \phi_i \right)$$

and

$$C_\tau = \sum_{i=1}^p \alpha_i C_{\tau-i} - \sigma^2 \left(1 - \sum_{i=1}^q \beta_i \phi_{i-\tau} \right), \quad \tau = 1, 2, \dots$$

The power spectrum of the same model is analogously

$$p(f) = \sigma^2 \frac{\left| 1 - \sum_{j=1}^q \beta_j e^{-2\pi i f j} \right|^2}{\left| 1 - \sum_{j=1}^p \alpha_j e^{-2\pi i f j} \right|^2}.$$

Useful in this context is also the partial autocorrelation $\gamma_{\tau\tau}$ of a stationary time series x_t which gives the correlation

between x_t and $x_{t-\tau}$ where the linear dependence on $\{x_{t-1}, \dots, x_{t-(\tau-1)}\}$ has been removed, i.e.

$$\hat{\gamma}_{\tau\tau} = \text{cor}(x_t, x_{t-\tau} | x_{t-1}, \dots, x_{t-(\tau-1)}).$$

Then plots of the autocorrelation and partial autocorrelations can give an indication of the AR and MA orders:

- For a stationary AR(p) process, the autocorrelations decay exponentially and the partial autocorrelations are zero for $\tau > p$.
- For a stationary MA(q) process, the autocorrelations are zero for $\tau > q$ and the partial autocorrelations decay exponentially.
- For a stationary ARMA(p,q) process, both, autocorrelations and partial autocorrelations, decay exponentially.

Figure 2 contains three samples of length 500 from an AR(1), MA(1), and ARMA(1,1) process with $\alpha_1 = \beta_1 = 0.6$ together with the corresponding estimated autocorrelation and partial autocorrelation functions. Values within the blue lines in the autocorrelation and partial autocorrelation plots are usually considered not significantly different from zero. Thus, the figure clearly shows how these functions can assist in order selection. Such visualizations of the (partial) autocorrelation function (acf) are often referred to as (partial) autocorrelogram.

As the periodogram contains the same information also its visualization can be used to get an idea of the order of ARMA processes, here the peaks and troughs of $\log(\hat{p}(f))$ are of interest. See Kitagawa (2010) for details. Rather than a graphical selection of the orders p and q , more common is to use model selection criteria such as AIC or BIC to select the order, and, for example, R (R Core Team 2020) has many tools to select ARMA orders and to estimate the coefficients.

Two concepts for AR and MA processes are still relevant. For an AR(p) process

$$1 - \alpha_1 x - \alpha_2 x^2 - \dots - \alpha_p x^p = 0$$

is called the AR characteristic equation. Similarly, for an MA(q) process

$$1 - \beta_1 x - \beta_2 x^2 - \dots - \beta_q x^q = 0$$

denotes the MA characteristic equation. An MA process is called invertible if all roots of the MA characteristic equation have an absolute value larger than 1. An AR process is only stationary when all roots of the AR characteristic equation also have absolute values exceeding 1. Thus in practical ARMA modeling to work in a stationary framework, it is

required that the AR part is stationarity and the MA part invertible. Invertibility for a time series means that we can transform it into an AR process, which means the time series can be expressed as a function of its past values. This is a key requirement when one is interested in predicting future values.

When we started out the modeling part, we assumed that the mean of the time series is constant and does not contain a trend. In many situations, however, where the nonstationary of the time series comes from the non-constant mean, taking differences of the time series makes it more stationary. The first-order difference is defined as $\nabla x_t = x_t - x_{t-1}$ and the d th-order difference repeats this d times and is denoted $\nabla^d x_t$. Using this approach to yield stationary ARMA processes was incorporated in the so-called autoregressive integrated moving average (ARIMA) models of order (p,d,q) which means that d th difference $\nabla^d x_t$ follows a ARMA(p,q) model. In most practical situations, d is either 1 or 2.

Figure 3 shows a sample of size 200 from an ARIMA(1,1,1) process with $\alpha_1 = \beta_1 = 0.6$ together with the first-order difference of the time series. While the original time series seems highly nonstationary, the differences look much more stable.

ARIMA models are nowadays the standard tool when starting time series models and can also be extended to allow for seasonal components. For further details about parameter estimation, model selection, and inference in the context of ARIMA models, see Brockwell and Davis (2020), Shumway and Stoffer (2017), and Hassler (2019).

Time Series Forecasting

One of the primary reasons for time series analysis is the prediction of future values, which is usually called forecasting. Based on the available history of the process, $x_1, \dots, x_t$, the goal is thus to forecast the value x_{t+l} , where t denotes the forecast origin and l the lead time. The forecast itself is then denoted $\hat{x}_{t+l}$ and should be preferably the minimum square error forecast given by:

$$\hat{x}_{t+l} = E(x_{t+l} | x_1, \dots, x_t).$$

Clearly, without strong assumptions, such a prediction is difficult. However if the process is Gaussian, it is known that the best predictor is a linear function of the available history. Assuming in addition an ARIMA process yields practical expressions for the predictions and the possibility to evaluate the uncertainties in the predictions by providing confidence intervals.

For stationary ARMA processes with $E(x_t) = \mu$, it holds that $\hat{x}_{t+l} - \mu$ decays to zero as lead l increases. Which means that the further one wants to predict the future, the more naive the forecast, approaching simply the mean value. This is however natural as the dependence in an ARMA process

Time Series Analysis in the Geosciences, Fig. 2 The top row shows from left to right a sample of $T = 500$ observations from an AR(1) process, a MA(1) process, and an ARMA(1,1) process where $\alpha_1 = \beta_1 = 0.6$.

The second row shows the corresponding sample autocorrelation functions and the third the partial sample autocorrelation functions

dies out, and only for shorter leads we can improve the naive forecast and benefit from the available data. Details about ARIMA predictions are found in Brockwell and Davis (2020); Shumway and Stoffer (2017); and Hassler (2019). Using the average monthly temperature data from Fig. 1, a seasonal ARIMA prediction for the years 2006 and 2007 is shown in Fig. 4 as the blue line. The shaded gray area reflects the uncertainty of the predictions. The actual observed average temperatures are given as the dashed black line and shows

that the predictions are quite good, just forecasted less cold winters, but the true values are still within the gray areas.

Various Extensions for Univariate Time Series

The ARIMA model with $d \in \{0, 1, 2\}$ with a possible seasonal adjustment is one of the standard tools in time series analysis. They are however not always suitable, and in the following, some different time series settings and models are discussed.

Time Series Analysis in the Geosciences, Fig. 3 The left panel shows a sample of size 200 from an ARIMA(1,1,1) process with $\alpha_1 = \beta_1 = 0.6$. The right panel shows the first-order difference of the same process

Time Series Analysis in the Geosciences, Fig. 4

The predicted average monthly temperature for the airport in Jyväskylä in C for 2006 and 2007 (blue line). The shaded area corresponds to the 95% prediction interval and the dashed black line are the observed average temperatures

Time Series with Long Memory. In the ARIMA model as discussed above, it assumed that the time series has a short memory which means that autocorrelation drops to zero after a certain lag or has an exponential rate of decay. For hydrological or meteorological time series like annual average rainfall, temperature, or river flow data, it can be however often observed that the autocorrelations are persistent over many lags. This persistence is then often denoted long memory. The extend of long memory is often quantified with the Hurst coefficient $H \in (0, 1)$ where 0.5 indicates the absence of long memory and a value larger than 0.5 indicates a persistent behavior. Long memory time series modeling can be embedded in an ARIMA framework by allowing the parameter d to take also fractional values, i.e., $d \in (0, 1)$, which is in detail discussed in Hassler (2019) and often denoted as fractional ARIMA modeling.

Nonlinear Time Series. The ARMA model introduced above is linear in its terms which is mathematically convenient and proved to be able to approximate many natural phenomena, however not all. Some processes in nature are just not linear. The literature on nonlinear time series models is quite large and an overview of different applications of nonlinear time series models in geosciences is, for example, given in Donner and Barbosa (2008). In the following, only two popular nonlinear time series models are introduced.

The simplest class of nonlinear models are piecewise linear models which are known as threshold models. In this class of models, it is thought that there is a set of K linear submodels and a mechanism that switches between the different submodels. A popular variant in this context is the threshold autoregressive (TAR) model which has the form

$$x_t = \alpha_0^{(j)} + \sum_{i=1}^p \alpha_i^{(j)} x_{t-i} + \beta^{(j)} \varepsilon_t,$$

where $j \in \{1, \dots, K\}$ is an indicator for the active submodel and the submodels have the parameters $\alpha_0^{(j)}, \dots, \alpha_p^{(j)}$ and $\beta^{(j)}$ and ε_t is a white noise process. Which submodel is active is indicated by the series z_t which takes values in $\{1, \dots, K\}$. If the state of Z_t depends only on the past values of x_t , i.e., $z_t = j$ if $x_{t-\tau} \in R_j$ for some fixed $\tau > 0$ with $\bigcup_{j=1}^K R_j = \mathbb{R}$, then it is a self-exciting TAR model. If however $z_t = j$ if and only if $y_{t-\tau} \in R_j$ where y_t is an observable or unobservable covariate time series, one says the TAR model is excited by y_t .

Another popular nonlinear model is the generalized autoregressive conditional heteroskedastic (GARCH) model. It can be formulated as

$$x_t = \sigma_t \varepsilon_t,$$

where ε_t is a white noise process and

$$\sigma_t^2 = \alpha_0 + \sum_{i=1}^p \alpha_i x_{t-i}^2 + \sum_{i=1}^p \beta_i \sigma_{t-i}^2$$

with model parameters $\alpha_i \geq 0, i = 0, \dots, p$, and $\beta_i \geq 0, i = 1, \dots, q$. Thus an ARMA(p,q) process is assumed for the variance of x_t , and for the series x_t , small values and large values should cluster.

Tests if nonlinear models are needed are well-established but have usually special nonlinear models as the alternative in mind. Similarly, parameter estimation and model selection for the above models are well investigated together with appropriate forecasting tools. For details about the above nonlinear models as well as many other methods, see, for example, Fan and Yao (2003).

Univariate time series methods from a geoscience perspective are, for example, also discussed in Gilje (2006).

Multivariate Time Series

So far, we have assumed that only one variable is measured at time t . For multivariate time series at the time t , a m -variate vector $\mathbf{x}_t = (x_1, \dots, x_m)^\top$ is observed. Thus, besides the serial dependence, also the dependence between the different variables need to be considered. The characteristics of the underlying stochastic process are then described using the expected value $E(\mathbf{X}_t)$, the covariance matrix $\text{Cov}(\mathbf{X}_t) = E((\mathbf{X}_t - E(\mathbf{X}_t))(\mathbf{X}_t - E(\mathbf{X}_t))^\top)$, and the autocovariance matrix $\mathbf{C}_\tau(\mathbf{X}_t) = E((\mathbf{X}_t - E(\mathbf{X}_t))(\mathbf{X}_{t-\tau} - E(\mathbf{X}_{t-\tau}))^\top)$. A key assumption is again that these quantities do not depend on the time, and multivariate (weak) stationarity is given when

$$E(\mathbf{X}_t) = \boldsymbol{\mu}, \quad \text{Cov}(\mathbf{X}_t) = \boldsymbol{\Sigma}$$

and

$$\begin{aligned} \mathbf{C}_\tau(\mathbf{X}_t) &= E((\mathbf{X}_t - \boldsymbol{\mu})(\mathbf{X}_{t-\tau} - \boldsymbol{\mu})^\top) \\ &= E((\mathbf{X}_{t-l} - \boldsymbol{\mu})(\mathbf{X}_{t-l-\tau} - \boldsymbol{\mu})^\top) = \mathbf{C}_\tau, \end{aligned}$$

for all τ and l . For an observed time series $\mathbf{x}_t, t = 1, \dots, T$ the corresponding sample statistics are:

$$\text{Empirical mean: } \hat{\boldsymbol{\mu}} = \frac{1}{T} \sum_{i=1}^T \mathbf{x}_i,$$

$$\text{Empirical covariance: } \hat{\boldsymbol{\Sigma}} = \frac{1}{T} \sum_{i=1}^T (\mathbf{x}_i - \hat{\boldsymbol{\mu}})(\mathbf{x}_i - \hat{\boldsymbol{\mu}})^\top$$

and

$$\text{Empirical autocovariance matrix: } \hat{\mathbf{C}}_\tau = \frac{1}{T} \sum_{i=\tau+1}^T (\mathbf{x}_i - \hat{\boldsymbol{\mu}})(\mathbf{x}_{i-\tau} - \hat{\boldsymbol{\mu}})^\top.$$

The empirical autocorrelation matrix is obtained as $\hat{\boldsymbol{\Gamma}}_\tau = D^{-1/2} \hat{\mathbf{C}}_\tau D^{-1/2}$ where the diagonal matrix D contains the diagonal elements of $\hat{\boldsymbol{\Sigma}}$.

The univariate ARMA model has been extended to the multivariate case and is usually referred to as vector autoregressive moving average (VARMA) model

$$\mathbf{x}_t = \sum_{i=1}^p \mathbf{A}_i \mathbf{x}_{t-i} + \varepsilon_t - \sum_{i=1}^q \mathbf{B}_i \varepsilon_{t-i},$$

where ε_t is an m -variate white noise process and the $m \times m$ matrices $\mathbf{A}_1, \dots, \mathbf{A}_p$ and $\mathbf{B}_1, \dots, \mathbf{B}_q$ are autoregressive and moving average coefficients, respectively. The special case VARMA(p,0) is correspondingly referred to as vector autoregressive process VAR(p) and VARMA(0,q) as vector moving average process VMA(q). The conditions for stationarity and invertibility translate similarly to the multivariate case as do order determination, and one can choose again to consider the problem from a time or frequency point of view. For details, see, for example, Wei (2019) and references therein. A big challenge in multivariate time series is however that already for small values of m , the number of parameters to estimate is quite considerable.

Therefore often dimension reduction methods are of interest in a time series context. On the one side is the dynamic factor model which is especially popular for financial data, and for details, we refer to Hallin et al. (2020). The approach presented here is based on blind source separation (BSS). In BSS, it is assumed that the observable m -variate time series $\mathbf{x}_t$ is a linear mixture of m latent unobservable processes $\mathbf{s}_t = (s_1, \dots, s_m)^\top$. The model can thus be written as

$$\mathbf{x}_t = \boldsymbol{\Omega} \mathbf{s}_t + \boldsymbol{\mu},$$

where the full rank $m \times m$ matrix $\mathbf{\Omega}$ is the mixing matrix and $\boldsymbol{\mu}$ is the m -variate location vector. The goal in BSS is to estimate $\mathbf{s}_t$ based on $\mathbf{x}_t$ alone. Clearly, for that more assumptions are needed. The two basic assumptions are $E(\mathbf{s}_t) = \mathbf{0}$ and $\text{Cov}(\mathbf{s}_t) = \mathbf{I}_m$. However, a third assumption is required, and this third assumption distinguishes between different BSS approaches. A review of BSS methods in the context of time series is, for example, Pan et al. (2021), and in the following only the main principles are introduced.

In the first approach, it is assumed that all m latent processes are weakly stationary linear time series which have different autocovariance functions, i.e., $\mathbf{C}_\tau(\mathbf{s}_t) = \mathbf{D}_\tau$ where $\mathbf{D}_\tau$ is a diagonal matrix where the diagonal elements depend on τ . This model is called the second-order source separation (SOS) model as the separation can be based on second moments alone. For example, AMUSE finds an unmixing matrix $\mathbf{\Gamma}$ as the matrix which simultaneously diagonalizes the covariance matrix and one autocovariance $\mathbf{C}_\tau$ in the sense that

$$\mathbf{\Gamma} \text{Cov}(\mathbf{x}_t) \mathbf{\Gamma}^\top = \mathbf{I}_p \quad \text{and} \quad \mathbf{\Gamma} \mathbf{C}_\tau(\mathbf{x}_t) \mathbf{\Gamma}^\top = \mathbf{\Lambda}_\tau,$$

where $\mathbf{\Lambda}_\tau$ is a diagonal matrix depending on τ . Such simultaneous diagonalization of two matrices can be solved via a generalized eigenvector-eigenvalue decomposition. The decomposition is however only unique if the autocovariances of $\mathbf{s}_t$ are all distinct at the chosen lag τ and therefore the performance of AMUSE depends a lot on its choice. To be less dependent on this choice, the SOBI method suggests to jointly diagonalize K autocovariance matrices plus the covariance matrix. This is nowadays considered a better approach and the added computational complexity is then negligible.

However, for example, in the case of GARCH processes, there is no information in the second moments and higher-order moments are of interest. The third assumption is then generalized in that way that the m latent processes are uncorrelated at all second and fourth (cross)moments, where cross-moments mean computing these moments between observations measured at different time points. In that case, methods like vSOBI and gSOBI extend SOBI by taking higher-order moments into account in the joint diagonalization process.

The third approach assumes that all m latent components have a constant mean, but their variances change over time and the constraint of identity holds only on average for the observed time span $1, \dots, T$. In that case, the model is called nonstationary source separation (NSS) and the idea for an unmixing matrix is to divide the observed time series into $K \geq 2$ non-overlapping intervals. The method NSS-JD then jointly diagonalizes the K covariance matrices obtained from the intervals under the constraint that the total covariance matrix must be the identity. Similarly, NSS-JD-TD chooses, in addition to the K covariance matrices, from the intervals additional autocovariance matrices for selected lags

computed on the separate intervals to be jointly diagonalized under the same constraint.

Given an unmixing matrix estimate, the components $\hat{\mathbf{s}}_t = \hat{\mathbf{\Gamma}}(\mathbf{x}_t - \hat{\boldsymbol{\mu}})$ are computed. Note that none of the BSS methods can recover actually the order of the components and their signs, but this is not relevant for the purpose of BSS which is threefold:

1. The estimated components might be easier to interpret and might give a better impression of the different underlying dynamics. For interpretations in relation to $\mathbf{x}_t$, the loadings from the unmixing matrix can be interpreted similarly as the loadings, for example, in PCA.
2. As the components are assumed uncorrelated, and often even the stronger assumption of independence is made, it is possible to model the m latent components separately from the others. Thus, no multivariate models need to be fitted but one fits m univariate models. This is often considered easier and more flexible.
3. It is often the case that not all m latent components are of interest and some might be simply noise. Thus dimension reduction can be performed by concentrating in the remaining analysis on the interesting components.

One type of data that is by definition multivariate is compositional data. Naturally, compositional data can also be observed over time which is usually denoted then as a compositional time series (CTS). To address the special nature of compositional observations, usually the compositions are first transformed into a coordinate system that follows a Euclidean representation, and then standard multivariate methods can be applied. The same strategy is usually also used for CTS. Kynclova et al. (2015) discuss vector autoregressive models in the context of CTS, while Nordhausen et al. (2021) investigate the use of blind source separation models in that context.

Functional Time Series

If an almost continuous time series can be divided into natural non-overlapping consecutive intervals, one can consider it as a series of ordered curves. Such a series of curves is known then as functional time series. Consider, for example, data coming from a magnetometer. Such a device measures almost continuously the magnetic field which depends heavily on the rotation of the earth. Hence it seems natural to look at the shape of these values based on the time of the day, i.e., the position of the sun, and therefor one has for each day one curve. Such a curve is then denoted $\chi_t(u)$, where t indicates the day and u the time of the day. Usually, it is assumed that the χ_t 's are elements of Hilbert spaces, and descriptive statistics are the functional mean, the covariance operator, and the autocovariance operator which can often be obtained by pointwise evaluations.

While the standard ARMA model has been extended to the functional setting, research mainly focuses on functional autoregressive (FAR) models for which order estimation and forecasting tools are well established. For further details, we refer to Kokoszka and Reimherr (2017) and references therein.

Software

As time series analysis is a common task in many fields, most statistical software packages provide tools to visualize and summarize time series. Similarly estimation and forecasting tools are usually also available. All the methods described here are, for example, available in R R Core Team (2020), and there is an R TASK VIEW dedicated to time series analysis listing the most important functions and packages; see <https://CRAN.R-project.org/view=TimeSeries>.

Summary

In geosciences many measurements are taken at regular intervals, and of interest is to understand the dynamics in the underlying processes and to have an idea of what will happen in the future. Depending on the nature of the data, there is a large selection of time series methods available. For simplicity, usually the modeling starts with stationary linear models. If these models are then not adequately describing the phenomena under consideration, different possibilities exist to address possible flaws like relaxing the requirements of stationarity and/or linearity.

Tobler, Waldo

Michael Batty
University College London, London, UK

Fig. 1 Waldo Tobler (1930–2018), From Wikipedia © By-SA 3.0

Biography

Waldo Tobler (1930–2018) was born in Portland, Oregon of Swiss parentage. He grew up in Seattle, but at the beginning of World War II, his father who was a consular official in the Swiss Embassy, moved to Washington DC. At the end of the war, the family returned to Bern in Switzerland where Waldo joined the American Army. He learnt several new languages including Russian and he was in the one place where he could

begin to indulge his lifelong interest in maps. On his discharge from the Army, he returned to North America, attending the University of British Columbia as an undergraduate. In 1957 he went to the University of Washington, Seattle where he joined one of the most select groups of Ph.D. students that has ever existed within geography. Almost single-handedly, they led what came to be called the “Quantitative Revolution.” Under the tutelage of Bill Garrison, Waldo with his Ph.D. student colleagues Brian Berry, Richard Morrill, Duane Marble, John Nystein, Arthur Getis, among others, laid out the ground work for a generation who began to use mathematics and the scientific method in the construction of a grand theory. This tied location theory to social physics providing, along the way, powerful theories that would enable rigorous transformations of the way space could be ordered, articulated, and visualized.

Out of all this came spatial analysis and geographic information systems as well as demographic, economic, transportation and many other models of the urban and regional system. Computers were key to making these developments possible. Waldo’s early work was on map projections and cartograms and the skills that he built up enabled him to develop many different transformations of the way one could construct and project maps, color them, and visualize them. Drawing on concepts from classical physics, in particular models of fluid flow, one of the central concepts he developed was the idea of representing vectors of movement between places defining what he called “interaction winds.” This tied his work to spatial interaction models and in this sense he thought about how such models might be built for a world of flows between places, which, as we know, are largely asymmetric. Waldo of course being a cartographer, was one of the first to produce rapid visualizations, and in one of his path-breaking papers (Tobler 1970), he introduced a dynamic model of the Detroit region, which made extensive use of early computer graphics using storage tubes and I had the privilege of seeing the model in action when I visited him in Ann Arbor in 1974. The paper describing the model not only introduced cellular automata modeling into the geography but also coined what has come to be called Tobler’s Law. In the paper, the model he developed was based on the key spatial principle that “. . . everything is related to everything else, but near things are more related than distant things.” It was almost a throw-away-line but it quickly came to be enshrined as his “Law.”

His first appointment after his time in Seattle was at Michigan where he was a faculty member from 1961 to 1977. He did great work on cellular automata, flows, and on statistical map generalizations and variances during these years. When the new department of geography was resurrected at the University of California at Santa Barbara (UCSB) in 1979, he moved to join that august group where he spent the rest of his academic career. There he developed many interesting

and, often it would appear, idiosyncratic mathematical and statistical applications based on patterns and flows. But for me, his great work during these later years was his focus on migration. He resurrected Ravenstein’s Laws and I am the proud possessor of a copy of his enlargement of Ravenstein’s famous map of migration flows from the 1881 British census. Waldo digitized, enlarged, colored the vector flows by hand, and the map hangs in my office in University College. He knew I was interested in this as after I went to America in 1990 to the National Center for Geographic Information and Analysis, which was headquartered at UCSB, we talked a lot about our interests in visualization, cellular automata, and how we might get computers to make sense of all this. In fact, I first met Waldo in 1974 much earlier when he came to the University of Reading to look me up, on spec so it seemed, while he was in the UK at a conference in Nottingham. In fact, he was really visiting Peter Hall who on the day in question was nowhere to be seen. I could have never imagined him coming to see me. He was one of the greats whose papers I had read but who I simply assumed in those far off days, I would never meet. But I had published a paper called “Spatial Entropy” in the journal *Geographical Analysis* that year and he was intrigued. It so happened that I was just about to depart to spend a year at the University of Waterloo. I then visited him and Gunnar Olsson at Ann Arbor in Michigan that same year, not far away from Waterloo, thence traveling with them to the North American meetings of the Regional Science Association in Chicago. It was a baptism of intellectual fire.

I last saw him at Keith Clarke’s house in Santa Barbara in February 2013 and then in that same year in April at the Annual Meetings of the Association of American Geographers in Los Angeles. He told me he was not going to travel any longer to meetings and our paths did not cross again. He was, in fact, the founder of analytical cartography. He was one of the first geographers to be elected to the National Academy of Sciences but he was recognized most for being what one might call an “academics academic,” a very learned man with a subtle sense of humor, some might almost say “wicked” at times and a conviction in his research that was bolstered by his many other interests. These ranged from hiking in the lowlands of California to the Swiss Alps, from classical music to a wide interest in everyone else’s academic indulgences. He was a colleague who would give his time to talk to anyone who took an interest in his work and he would always reciprocate. A giant in the field.

Topology in Geosciences

Florian Wellmann

Computational Geoscience and Reservoir Engineering,
RWTH Aachen University, Aachen, Germany

Definition

Topology is a sub-branch of geometry, concerned with relationships between objects that remain unchanged under certain types of deformation (such as stretching, bending, twisting, and shrinking). Objects that can be transformed into each other under such transformations are topologically equivalent. The two objects are then said to be homeomorphic. In a general sense, homeomorphism is a function that provides a mapping between two objects which are topological equivalent.

Introduction

Compared to *geometry*, topology is a relatively recent field of study. It emerged only in the eighteenth century based on the pioneering works of Leonhard Euler and Gottfried Leibniz, but became quickly an important and independent field of study (e.g., Earl 2019). While geometry is the study of objects in space, topology is the study of how objects are connected, in a more abstract point of view. In geology, these relationships are often derived from geological events in the local history – e.g., sedimentary deposition, magmatic intrusions, metamorphic overprinting, or deformation in tectonic events. Note that these relationships between surfaces (2-manifolds) are low-dimensional topologies. A simple general example is the connectivity in letters of the alphabet (Fig. 1a). The letters in each row (with this specific choice of font) can be transformed into each other by stretching and bending of the line segments. In topology terminology, the letters in each row are *homeomorphic* to each other. Note the important difference to the geometric term congruence: the letters cannot be transformed into each other through a combination of translation, rotation, or reflection. The important difference between the letters in each row is the number of *T-junctions*, highlighted with red dots in Fig. 1a: these junctions denote a fundamental difference between the letters that cannot be removed through processes of stretching and bending.

Another popular example is the math pun that a topologist cannot tell the difference between a coffee mug and a doughnut: both objects have one hole and can be transformed into each other through processes of stretching and bending, they are *topologically invariant* (Fig. 1b). This type of invariance

under stretching and bending has also led to the description of topology as “rubber sheet geometry.”

This abstract view of objects and their relationships has important applications in mathematics and physics, and the concepts have been applied to geoscientific investigations. Some basic principles and their applications are described in the following.

Euler’s Formula

The mathematician Euler was one of the first to investigate topological concepts with rigor in his study on the relationship between vertices, edges, and faces in closed polyhedra. In one of the first proofs in the field of topology, he could prove that there exists a fixed relationship in these objects, which is today known as Euler’s formula:

$$V(\text{vertices}) - E(\text{edges}) + F(\text{faces}) = 2 \quad (1)$$

This relationship is directly obvious when we consider a common cube in 3-D (Fig. 2a). It is easy to see that Euler’s formula is valid here, with 8 vertices, 12 edges, and 6 faces ($8 - 12 + 6 = 2$). When we insert a new vertex (Fig. 2b), we obtain triangular faces in addition to the quadrilateral ones in the regular cube, resulting in 9 vertices, 16 edges, and 9 faces ($9 - 16 + 9 = 2$). The principle is also valid for more complex objects, for example, a low-polygon version of the Stanford Bunny in (Fig. 2c) with 157 vertices, 464 edges, and 309 faces ($157 - 464 + 309 = 2$).

Other types of geometric objects can equally be identified by their value in the Euler formula, commonly referred to as Euler characteristic. Closely related to the Euler characteristic is the term genus, which, broadly speaking, describes the number of holes in a surface (a torus has genus 1, whereas a sphere has genus 0). More examples are provided in Table 1.

The fundamental idea to analyze systems based on relationships that remain unchanged under certain types of deformation such as stretching and folding and the related comparison of objects based on topological invariants can be applied to a range of geoscientific questions. Examples are outlined in the following.

Topological Analyses of Connectivity

Geoscientific analyses are often concerned with connections between objects, for example between bodies with different rock properties or faults in fault networks. Egenhofer and Herring (1990) provided a fundamental treatment of the possible relationships between two cells A and B in space based on the comparison of the interiors (A^0, B^0), the boundaries ($\partial A, \partial B$), and the exteriors (A^-, B^-) of these objects. With all possible combinations, this leads to the definition of the possible topological relationships in the *9-intersection-model* (9IM), also referred to as the Egenhofer-Matrix:

Topology in Geosciences,

Fig. 1 Examples of topological concepts: (a) letters with different numbers of junctions; (b) coffee cup and doughnut

(a) Letters

(b) Coffee cup and doughnut

**Topology in Geosciences,**

Fig. 2 Euler's formula for different objects: (a) common 3-D cube; (b) cube with one inserted vertex; (c) low-polygon model of the Stanford bunny

$$w(A, B) = \begin{pmatrix} A^0 \cap B^0 & A^0 \cap \partial B & A^0 \cap B^- \\ \partial A \cap B^0 & \partial A \cap \partial B & \partial A \cap B^- \\ A^- \cap B^0 & A^- \cap \partial B & A^- \cap B^- \end{pmatrix} \quad (2)$$

The entries in this matrix are either true (T) or false (F). Cell relationships with the same intersection matrix are topologically equivalent. An extension of this concept that includes the dimensionality of the intersections has been proposed by Clementini and Di Felice (1996). This model has been adapted for spatial data query concepts and is implemented in GIS-systems.

With the 9 Boolean entries in the matrix, a total of $2^9 = 512$ relationships would theoretically be possible. However, only a subset of these matrices is meaningful to describe topological regions. More specifically, if we limit the view to simple regions with a connected boundary separating interior and exterior parts in 2-D (i.e., regions that are homeomorphic to a unit closed disc), only 8 relationships are realizable (Fig. 3).

The same relationships exist between two 3-D regions in 3-D space (Zlatanova et al. 2004). Extensions to more general cases are possible (Li 2006).

Application to Structural Models

The most basic aspect in the context of geoscientific investigations often concerns the question if two cells (e.g., geological bodies) are connected or not: a typical example is a full space-filling tessellation with non-overlapping domains (also referred to as a water-tight discretization). In this case, a first-order relationship between discrete cells can be derived in the form of a connectivity graph (also referred to as topology graph), where nodes represent the cells and edges the neighboring relationship between two cells. Note that other representations are possible, for example on the basis of shared boundaries or nodes (see Thiele et al. 2016, for more examples).

Topology in Geosciences, Table 1 Euler characteristic numbers for some typical shapes

Type	$V - E + F$	Genus	Representation
Sphere (and all closed polyhedra)	2	0	
Torus (and, famously, a coffee cup) tabular	$0 - 2 + 2 = 0$	1	
Double torus	$0 - 4 + 2 = -2$	2	
Line with vertices	$2 - 1 + 0 = 1$	–	
Circle (line closed at same vertex)	$1 - 1 + 0 = 0$	–	
Disc	$1 - 1 + 1 = 1$	–	

The concept to use connectivity graphs (also based on the intersection model) has been applied to a range of investigations in the field of structural geology and geomodeling.

A typical example is provided in Fig. 4 with a topology graph (Fig. 4b) encapsulating the connectivity of geological bodies in a 3-D structural model framework (Fig. 4a).

The concept of connectivity graphs can be extended to consider the specific type of relationship between the objects. In the case of an analysis in the context of geological models, typical relationships would be a simple continuous stratigraphic succession, a contact related to an unconformity, an intrusive contact, or a connection across a fault (Thiele et al. 2016). On this basis, it is then also possible to distinguish a connectivity graph based on differences in lithology (lithology graph) from a connectivity graph for different structural domains, separated by faults.

In addition to the purely static analysis of connectivity in geological models, it is also possible to decipher the temporal relationship in the form of geological events. A fundamental framework for such a temporal geological event analysis has already been proposed by Burns (1975) and can be used to analyze geological event sequences from geological maps (e.g., Jessell et al. 2021). Such a topological analysis considering the time evolution can be considered as a temporal topology, in distinction to the purely spatial topology described above (e.g., Thiele et al. 2016).

Topology of Fault and Fracture Networks

Methods of topology have also been used to describe connectivity in fracture networks. The motivation to use topology here comes from the strong links between connectivity and flow, as an essential aspect in the analysis of fracture networks, which is often more important than the exact geometry of the fracture network itself (e.g., Manzocchi 2002; Sanderson and Nixon 2015; Sanderson et al. 2019). In 2-D space, Manzocchi (2002) defined different types of line intersections that are relevant in the characterization of a fracture network:

X-nodes points at intersections of two lines, where both lines extend beyond the intersection point itself.

Y-nodes (also: T-nodes): points at a T-shaped intersection between two lines (i.e., one line ending at the intersection point). This type of node is also an indication of an age relationship.

nodes isolated line end points.

These three node types can be related to different types of fracture systems and used as a classification Scheme. A simple example is presented in Fig. 5 with a fracture network analysis on the basis of these three types of nodes. The node ration can be visualized in a ternary diagram for comparison with other types of fault, joint, and fracture

T

Topology in Geosciences, Fig. 3 Topological relationships that can be realized between simple regions with examples in 2-D and 3-D and the corresponding matrix entries (1 = true, 0 = false)

Topology in Geosciences, Fig. 4 Example of a geological model (a) and the corresponding topology graph (b). (From Schaaf et al. (2021))

networks and with theoretical fault network models with different types of length distributions (Manzocchi 2002).

Based on these node classifications, a number of summary statistics can be calculated (e.g., Nyberg et al. 2018):

- Number of branches $N_B = \frac{N_I + 3N_Y + 4N_X}{2}$
- Number of lines $N_L = \frac{N_I + 2N_Y}{2}$
- Average connections per branch $C_B = \frac{3N_Y + 4N_X}{N_B}$

Topology in Geosciences,

Fig. 5 Example of a fracture network topology analysis: (a) schematic view of a fracture network with isolated nodes (red), nodes at truncated fractures (blue), and nodes at intersection points (green); (b) ternary diagram showing the node types

An important aspect here is that the important characteristics of these networks with respect to connectivity and, therefore, fluid flow would remain unchanged under purely continuous deformation of the space (i.e., only considering stretching, rotation, shearing, with no change in topology). This aspect enables then an investigation of connectivity and fluid flow through the investigated network in a previous point in time, where the geometry of the fracture network itself may have been different.

The topological description itself can also be extended to an analysis using methods from graph theory (Sanderson et al. 2019), for example, enabling a consideration of fracture width through edge weights, and directed graphs, if flow directions are known (e.g., on the basis of simulations).

Summary

Topology evolved over the last century from a mostly fundamental mathematical topic to an area of active research with a wide range of applications. In the field of geosciences, notable applications are in the area of network analyses for geological maps and models, fault and fracture networks, as well as river and Karst systems, and in geomorphological analyses. In all of these examples, the aim is to find a scientifically relevant abstraction of a geoscientific system using topological descriptions and methods. Examples are the simplification of a river system to inflow linkages or the abstraction of a complex geological model to cells which are in contact with each other. The motivation for the abstraction is here to limit the view to the dominating aspect that is relevant for fluid flow, for example, and to relate these essential characteristics to generic concepts. Similar aspects are behind the motivation to describe fault networks with connectivity graphs. Similar to the connectivity analyses shown above, topological connectivity analyses have also been used to analyze river networks (e.g., Mantilla et al. 2010) and connectivity in Karst

systems (e.g., Collon et al. 2017). Topological concepts are also widely used in a variety of operations in Geographic Information Systems (GIS) analyses (e.g., Phillips et al. 2015).

In a wider context, the field of topology goes far beyond these current applications in geosciences. This is evident in the 2016 Nobel Prize in Physics, which was awarded to a team of scientists who pioneered the use of topological concepts for a better understanding of phase transitions in condensed matter physics. Two important sub-fields of topology are differential topology and algebraic topology. Differential topology addresses the general topological study of smooth maps and manifolds. In contrast to differential geometry, the focus is not on geometric aspects, such as angles and curvature but on broader aspects such as the number of holes in a manifold. Important terms related to this topic are homotopy type and diffeomorphism groups. Algebraic topology is an extension of these concepts using methods from algebra to investigate topological spaces, extending the concepts of homology to homological algebra and linking methods of topology to algebra. The related field of knot theory, also a sub-branch of topology, investigates the embedding of knots from an abstract mathematical viewpoint, with applications to quantum physics or biological structure investigation. The transfer of these concepts to geoscientific research questions is surely an interesting path for future research.

Total Alkali-Silica Diagram,

Fig. 1 Scatterplot defining the names of 15 different types of volcanic rocks. Tephrite or basanite are two alternative names for the same type of rock. The same is valid for trachyte or trachydacite

Total Alkali-Silica Diagram

Ricardo A. Olea

Geology, Energy and Minerals Science Center,
U.S. Geological Survey, Reston, VA, USA

Definition

The total alkali-silica (TAS) diagram is a scatterplot of the chemical concentrations of silica oxide (SiO_2) versus total alkali-sodium oxide (Na_2O) plus potassium oxide (K_2O) – in volcanic rocks (Fig. 1). This graph is used as a template for classifying volcanic rocks based on measured chemical concentrations when fine-grain size makes determining the mineralogic composition difficult to impossible. Under this provision, the TAS diagram is supported by the International Union of Geological Sciences Subcommittee on the Systematics of Igneous Rocks (Le Maitre 2002). As an example, if a volcanic rock has 49.8% SiO_2 and 4.1% alkali oxides, it is classified as basalt.

Properties

The TAS diagram is the results of international efforts and was preceded by several other similar diagrams postulated by various petrologists (Le Bas et al. 1992). By the time the TAS

diagram was released, there was a general consensus on the names of most types of volcanic rock. There were, however, problems with details. Over the years, Le Maitre and Ferguson (1978) had assembled a large database with over 15,000 analyses taken from the literature, each one with its geochemical composition and rock name assigned by the person(s) responsible for each analysis. Plots were prepared for each rock type to observe tendencies and dispersions. The centroid for each tile in Fig. 1 were selected to be as close as possible to the center of gravity for their corresponding point clouds, which were created by plotting information from the database on the same axes. It was further agreed that boundaries between tiles would have to be straight lines, and that the coordinates for their extremes, as much as possible, should be integer numbers.

Only rocks with analyses showing less than 2% water and less than 0.5% CO₂ were used in the preparation of the diagram. If both of those two components were present in concentrations below their respective cutoffs, the concentrations of water and CO₂ were discarded, and the rest of the proportions rescaled to add to 100%.

Summary and Conclusions

The TAS diagram is a graphical tool for the consistent naming of volcanic rocks. The diagram summarizes prior conclusions reached by multiple petrologists over several decades. The class boundaries are far from arbitrary since they represent the results of an international consensus.

Trend Surface Analysis

Frits Agterberg
Central Canada Division, Geomathematics Section,
Geological Survey of Canada, Ottawa, ON, Canada

Definition

Trend surface analysis is an early geoscientific application of the general linear model of mathematical statistics. It can be

regarded as the two-dimensional extension of polynomial curve-fitting. Suppose that the geographic coordinates of a point are written as u and v for the east-west and north-south directions, respectively. An observation made at a point k can be written as $Y_k = Y(u_k, v_k)$ to indicate that it represents a specific value assumed by the variable $Y(u, v)$. In trend surface analysis, it is assumed that $Y_k = T_k + R_k$ where $T_k = T(u_k, v_k)$ represents the trend and R_k is the residual at point k . T_k is a specific value of the variable $T(u, v)$ with

$$T(u, v) = b_{00} + b_{10}u + b_{01}v + b_{20}u^2 + b_{11}uv + \dots + b_{pq}u^p v^q$$

In general, u and v form a rectangular coordinate system. However, latitudes and longitudes can also be used. In specific applications, $p + q \leq r$ where r denotes the degree of the trend surface. Depending on the value of r , a trend surface is called linear ($r = 1$), quadratic ($r = 2$), cubic ($r = 3$), quartic ($r = 4$), or quintic ($r = 5$). Higher-degree surfaces have also been used. A trend surface of degree r has $m = 0.5 \cdot (r + 1) \cdot (r + 2)$ coefficients b_{pq} . It is possible to extend the preceding equations from two to three dimensions.

Introduction

The method of trend surface analysis is one of the early applications of the general linear model in the geosciences (Krumbein and Graybill 1965). In the late 1960s, this technique was competing with universal kriging originally developed by Huijbregts and Matheron (1971). Today, both techniques remain in use for describing spatial trends or “drifts” in variables with a mean that changes systematically in two- or three-dimensional space. Simple moving averaging as practiced by Krige (1966) or inverse distance weighting methods can be equally effective when there are many observations.

Trend surface analysis was one of the first computer-based methods widely applied in geophysics, stratigraphy, and physical geography in the 1960s. Initially, it was assumed that the residuals from a best-fitting trend surface should be independent and normally distributed but Watson (1971) clarified that polynomial trend surfaces are unbiased if the residuals satisfy a stationary random process model. An early example of trend surface analysis is shown in Fig. 1. Davis (1973) fitted the linear trend surface shown in Fig. 1b to the contours of the top of the Arbuckle Formation in Kansas shown in Fig. 1a. The residuals, of which the average value is equal to zero, are shown in Fig. 1c.

Other examples of 2D trend surface analysis will be given in the following sections. They include variations in mineral composition (enstatite in orthopyroxene) in the Mount Albert Peridotite Intrusion, eastern Quebec. A 3D extension of the method applied to Mount Albert specific gravity data shows

Trend Surface Analysis, Fig. 1 Top of Arbuckle Formation in central Kansas. Contours are in feet below sea level (after Davis 1973). Geographic coordinates are in arbitrary units. (Area shown measures 320 km

on a side.) (a) Contour map of original data; (b) Linear trend surface; (c) Residuals from linear trend surface. (Source: Agterberg 1984, Fig. 1)

that, geometrically, serpentinization of this peridotite body occurred along a northward dipping inverted pyramid (also see later). Trend surface analysis can be applied to data that have been subjected to transformation as will be illustrated for copper concentration values in the Whalesback Mine, Newfoundland. In another example, mosaics of trend surfaces fitted to contours of the bottom of the Matinenda Formation, Elliott Lake area, northern Ontario, show residuals that are pathfinders for occurrences of uranium deposits.

By means of these examples, it will be illustrated that trend surface analysis can provide meaningful results for establishing: (1) regional trends by eliminating local distortions that are either due to localized random distortions of broad regional patterns or to measurement errors and (2) extracting meaningful patterns of residuals retained after eliminating regional trends that obscure these local patterns which are of interest for mineral exploration.

Mount Albert Example

The Mount Albert intrusion is the largest ultramafic mass (approx. 44 km²) in the Gaspé (Quebec) portion of the so-called Appalachian ultramafic belt. It is probably 530 my old. The intrusion was mapped and sampled in 1959 by C.H. Smith and I.D. MacGregor, who made their data available to the author for performing trend surface analysis (Agterberg 1964). The petrography of the body is relatively simple. Prior to serpentinization, it consisted of from 80% to 90% olivine, the remainder being primarily orthopyroxene with some chrome spinel (up to 1%) and diopsidic clinopyroxene. It was attempted to collect rock specimens from the nodes of a rectangular grid with 1000 feet spacing. The actual number of specimens that could be collected was less because of overburden. The number of mineralogical determinations was further reduced by serpentine alteration. The following four variables were determined for as many collected specimens as possible: (1) cell edge d_{174} of olivine; (2) refraction index N_z of orthopyroxene; (3) unit cell dimension of chrome spinel; and (4) specific gravity of the whole rock. The first two variables were converted into percentage magnesium in olivine and orthopyroxene, respectively, and the results reported as mol. percent forsterite (Mg-olivine) and enstatite (Mg-orthopyroxene). The relationship between percent serpentine and rock density in samples from the Mount Albert intrusion is approximately linear. Serpentinization was a process that continued after the ultramafic body was already in place. The specific gravity measurements range from 2.5 (nearly pure serpentine) to 3.3 (unaltered peridotite). In most of the study area, average specific gravity is about 2.7 indicating that, overall, about 75% of the original peridotite was altered into serpentinite.

For example, the cubic trend surface for percentage enstatite in orthopyroxene is shown in Fig. 2, along with its 95% confidence interval. It suggests that there occurs a %Mg maximum in the southeastern corner of the intrusion. The shape of the 95% confidence interval for this trend surface mirrors the boundary of the intrusion because all observation points are contained within this boundary. It confirms the existence of the elongated ENE-WSW trending %Mg minimum but not necessarily the maximum in the southeastern corner of the intrusion. There is a pocket of practically unaltered peridotite in the eastern part of the body where the transition from high-density to lower-density material is relatively rapid. Although the Mount Albert intrusion was originally a peridotite, later it became primarily a serpentinite body. Recently, serpentinites have become important as a probable means of widespread rapid carbon mineralization for permanent disposal of anthropogenic carbon dioxide emissions (Matter and Stute 2016). This warrants more detailed studies of the shapes of such bodies (cf. Deschamps et al. 2013) (Fig. 3).

A schematic contour map for Mount Albert elevation is given in Fig. 3a. A cross-sectional CD was constructed and in Fig. 3b all observations within 2500 ft from the section line were projected onto it. Then, average values for blocks measuring 5000 ft on a side were calculated (Fig. 3c). These block averages almost exactly coincide with the intersection of a separately fitted quintic trend surface with the cross-sectional CD. The percentage explained sum of squares (ESS) of the quintic trend surface amounts to ESS = 56.0%. This shows that (1) the quintic trend surface provides a good fit to the specific gravity trend and (2) a trend surface also can be

Trend Surface Analysis, Fig. 2 Outline of Mount Albert peridotite intrusion. Cubic trend surface for percent enstatite in orthopyroxene is shown together with locations of specimens and 95% half-confidence interval. (Source: Agterberg 1974, Fig. 43)

Trend Surface Analysis, Fig. 3 (a) Schematic contour map of Mount Albert Peridotite; elevations are in feet above sea level. (b) Variations in specific gravity along section CD (see A for location); all values within 2500 ft from section line were perpendicularly projected onto it. (c) and (d). Cubic trend surfaces for 3000-ft and 2000-ft levels obtained by contouring three-dimensional cubic hypersurface in two horizontal

planes. In most of the area, today's topography resembles the 3000-ft pattern more closely than the 2000-ft pattern. (e) Crosses represent averages for values within blocks measuring 5000 ft on a side (see b). Curve 1 is intersection of quintic trend surface (Fig. 7.6) with CD; curve 2 represents variation along topographic surface (see a) according to three-dimensional cubic hypersurface (Source: Agterberg 1974, Fig. 46)

obtained by the relatively simple method of moving averages. The method of moving or running averages consists of calculating arithmetic averages for a large number of overlapping blocks and contouring the results. Obviously, such method can only be applied when there are many observations. If few observations are available, trend surface analysis is to be preferred.

Because as many as 359 data points were available for specific gravity, 3D trend analysis can be attempted by incorporating the elevation of each observation point. The 3D cubic trend equation contains 19 explanatory variables ($u, v, w, u^2, uv, uw, v^2, vw, w^2, u^3, u^2v, u^2w, uv^2, uvw, uw^2, v^3, v^2w, vw^2$, and w^3) and 20 coefficients. Its ESS-value amount to 55.1% which is close to the previously mentioned ESS = 56.0% for the quintic trend surface. Calculated values for the 3D cubic along the topographic surface are shown for the CD profile in Fig. 3e. Because all observation points lie in the topographic surface, the elevation w could be approximated by a 2D polynomial in u and v . Consequently, a 3D trend $f(u, v, w)$ becomes a 2D trend $g(u, v)$ if w , as contained in $f(u, v, w)$, is replaced by its polynomial in u and v . The reliability of the 3D trend $f(u, v, w)$ decreases rapidly below the topographic surface. Figures 3c and d show extrapolations of the 3D cubic trend in the vertical direction obtained by setting w equal to 2000 ft and 3000 ft, respectively. This, of course, results in two ordinary cubic trend surfaces as shown in these two figures. Comparison with the contour map for the topographic surface (Fig. 3a) suggests the following interpretation. As mentioned before, specific gravity on Mount Albert is, by approximation, linearly related to volume percentage serpentine. Thus, a low value indicates a soft rock relatively sensitive to erosion. Two of the three rivers originating on Mount Albert follow zones of weakness at the 3000-ft. level rather than at the 2000-ft level. Further comparison with the contour map for elevation suggests present-day topography was controlled by the distribution of less weathering resistant rocks at higher levels. It can be concluded that the pipe of maximum serpentinization moved northward as well as upward.

Modeling of Residuals

As mentioned before, Watson (1971) pointed out that trend surface analysis produces valid result if the residuals are autocorrelated according to a functional relationship that is independent of location within the study area. In this section two examples of such autocorrelated residuals will be given. Both examples are based on a set of exploratory boreholes. The first is for copper concentration values in adjoining samples taken from along subhorizontal boreholes on the 425-ft mining level in the Whalesback copper deposit, Newfoundland. The second example consists of depth

measurements for the bottom of the Matinenda Formation, Elliott Lake area, northern Ontario, measured in boreholes drilled from the topographic surface downward for the purpose of finding uranium deposits.

The Whalesback copper deposit near Springdale, Newfoundland, provides an example of trend surface analysis in a situation that the values are autocorrelated and have a frequency distribution that is positively skewed with a long tail of large values. The orebody which later was mined out consists of chloritic altered volcanics containing pyrite and chalcopyrite mainly in disseminated form. However, these minerals also tend to cluster and form stringers and occur in well-defined narrow veins with maximum width of 1.2 m. The deposit coincides with a shear zone. It is about 400 m long at the surface. Average width of the central copper zone which averages more than 1% copper is approximately 20 m, and vertical depth is 270 m. The copper zone is enveloped by a rather strongly altered chlorite zone with 0.35% Cu on the average.

Trend surface analysis (Agterberg 1964) was applied to copper concentration values from the 425 ft level that occurs 425 ft below the surface. The core for underground drill holes, which were 50 ft apart, was divided into pieces of 5 ft length, and assay values (percentages copper) were determined from these. About 15 volume percent of the rocks in the deposit consist of dikes that do not contain copper. This yields zero assay values which were omitted from the data to be used for statistical analysis and trends will be projected across the dikes. Therefore, if average grade values are to be determined for larger blocks of ore, these values, after calculation, should be reduced by 15% for dilution caused by barren dikes. Of course, more precise corrections can be made in places where the precise location of dikes is known.

Because trend surfaces are imprecise at the edges of clusters of observation points, overlapping sets of six drill holes, or crosscuts which have been sampled in the same manner, were used, and quadratic and cubic trend surfaces $S(u, v)$ were fitted to logarithmically transformed copper values. The fitted values were converted back to ordinary copper values by using the transformation $T(u, v) = \exp [S(u, v) + s^2/2]$ where s^2 is the residual variance for the $S(u, v)$ surfaces. The central part for each converted surface $T(u, v)$ for a 150 ft wide zone situated between the second and fifth hole in each situation is shown in the mosaic of Fig. 4 for the cubic trend surface. This transformation assumes that at any location the copper values are lognormally distributed with mean $T(u, v)$ and logarithmic variance s^2 . Figure 4 shows histograms of the natural logarithms of the original 516 copper values and also of the residuals from the cubic trend surface. Autocorrelation of residuals affects the results of trend surface analysis. The variance of the mean of n autocorrelated data from a series with the first order Markov property satisfies

$$\begin{aligned}\text{var}(\bar{X}) &= n^{-2} \sum_{i=1}^n \sum_{j=1}^n \text{cov}(X_i, X_j) \\ &= \sigma^2 \left[1 + 2 \frac{\rho}{1-\rho} \left\{ (1-n^{-1}) - \frac{\rho}{1-\rho} (1-\rho^{n-1}/n) \right\} \right] / n\end{aligned}$$

where ρ is the autocorrelation coefficient for adjoining values (cf. Cressie 1991, p.14). Suppose an equivalent number of independent data (n') is defined as $\text{var}(\bar{X}) = \sigma^2/n'$. For $n > 10$, the preceding equation then gives approximately

$$n/n' = 1 + 2r_1 \left[n/(1-r_1) - 1/(1-r_1)^2 \right] / n$$

(cf. Agterberg 1974, p.302). For large n this gives $n' \approx n(1-r_1)/(1+r_1)$ illustrating that autocorrelation strongly affects statistical inference even in large samples. In Agterberg (2014) it is discussed in more detail that (a) the residuals in Fig. 5b are approximately normally distributed and (b) a good estimate of the autocorrelation of the residuals

Trend Surface Analysis,

Fig. 4 Mosaic of exponential cubic trend surfaces for copper concentration value on the 425-ft level of Whalesback Mine; based on underground borehole data; drill holes were north-south oriented, approximately 50 ft apart. (Source: Agterberg 1974, Fig. 49)

Trend Surface Analysis, Fig. 5 (a) Histogram of natural logs of 516 copper values; (b) ditto for residuals from cubic trend surfaces shown in Fig. 4; this frequency distribution is approximately Gaussian. (Source: Agterberg 1974, Fig. 51)

is $r_1 = 0.50$. Consequently, $n' = n/3 = 172$ illustrating the strong effect of autocorrelation of the residuals.

The second example of the preceding trend+signal+noise model is for the Elliot Lake area (Figs. 6, 7, and 8). The following is a brief summary of this statistical analysis previously published in Agterberg (1984). Figure 6 shows contours of parts of eight quadratic trend surfaces fitted to depth measurements of the bottom of the Matinenda Formation in boreholes of which the locations are shown in Fig. 7. In this area the Archean basement rocks of the Canadian Shield are unconformably overlain by Proterozoic rocks which later were subjected to folding. This resulted in the Quirke Syncline of which the axis is shown as a trace in Figs. 6, 7, and 8. Locally, the bottom of the Matinenda Formation contains uranium mineralization. In Fig. 7 the squares indicate boreholes in which significant uranium mineralization was encountered and the triangles represent other boreholes. The quadratic trend surfaces were fitted to these data from overlapping clusters of observation points. Figure 8 shows the

sum of this trend and the signal. The strong similarity of patterns in Figs. 6 and 8 illustrates that changes in magnitude of the signal (Fig. 8) are small in comparison with those of the trend (Fig. 6).

Robertson (1966) had attempted to reconstruct the topography of the top of the Archean basement as it was before the later structural deformation. He assumed that the Matinenda formation was deposited in topographical depressions in the top of the basement. This geological model provides a good reason for application of the trend+signal+noise model introduced in the previous section. Ideally, the trend in this model would represent the structural deformation and the signal would represent the original topographical surface on which the Matinenda Formation was deposited. Thus, it would be meaningful to extract the signal from the data by elimination of (1) the trend and (2) the noise representing irregular local variability which is unpredictable on the scale at which the sampling (by drilling) was carried out.

Trend Surface Analysis,

Fig. 6 Contours (in feet above sea level) of parts of eight quadratic trend surfaces fitted to separate parts of bottom of Matinenda Formation, Elliot Lake area. Trace of axial plane of Quirke Syncline is shown also. Archean basement rocks are shown by pattern. Universal Transverse Mercator grid locations of corner points of map area are shown in km. (Source: Agterberg 1984, Fig. 8)

Trend Surface Analysis,

Fig. 7 "Signal" for bottom of Matinenda Formation, Elliott Lake area, Ontario, obtained by contouring kriging values (in feet) computed at points with 1 km-spacing. Squares and triangles represent locations of drill holes with and without significant mineralization, respectively. (Source: Agterberg 1984, Fig. 7)

Trend Surface Analysis,

Fig. 8 Sum of trend (see Fig. 6) and signal (see Fig. 7) for bottom of Matinenda Formation. Note strong resemblance between patterns of Figs. 6 and 8 illustrating that the fluctuations (signal) contoured in Fig. 7 have relatively small magnitudes. (Source: Agterberg 1984, Fig. 9)

The following procedure was followed to obtain a 2D autocorrelation function for residuals from the trend shown in Fig. 6. By using polar coordinates, distances between pairs of boreholes were grouped according to (1) distance (1-km spacing) and (2) direction of connecting line (45° wide segments). This gave domains of different sizes. Autocorrelation coefficients for pairs of values grouped according to this method were assigned to the centers of gravity of their domains. A 2D quadratic exponential (Gaussian) function with superimposed noise component (nugget effect) was fitted by trend surface analysis of logarithmically positive autocorrelation coefficients obtained from the grouped data. Both the input pattern of autocorrelation coefficients and the fitted function are symmetrical with respect to the origin where the observed autocorrelation coefficient is equal to 1 because it includes the noise component. A profile through the origin across the quadratic trend surface fitted to logarithmically transformed autocorrelation function is a parabola with its maximum at the origin. Each parabola becomes a Gaussian curve when the antilog is taken. The maximum of the fitted function fell at 0.325 indicating that only 32½ % of the variance of the residuals is explained by the signal versus 67½ % by the noise. The function has elliptical contours which are elongated in approximately the NW-SE direction. This directional anisotropy would indicate that the actual topography features (channels?) which constitute the signal are elongated in the NW-SE direction.

The signal was extracted from the residuals by using the theoretical autocorrelation function. The kriging method was used to estimate the values of the signal at the intersection points of a grid (UTM grid) with 1-km spacing. Every kriging value was estimated from all observations falling within the ellipse described by the 0.01 contour of the theoretical Gaussian autocorrelation function. This ellipse is approximately 13 km long and about 7 km wide. The estimated kriging values on the 1-km grid defined a relatively smooth pattern which was contoured yielding the pattern of Fig. 7.

Summary and Conclusions

Trend surface analysis is a useful application of the general linear model when the dependent variable of interest shows broad regional changes that can be modeled by using simple polynomial functions of the geographical coordinates. In this chapter a two-dimensional application was given using enstatite content of pyroxene crystals in the Mount Albert Peridotite intrusion in Québec. Most of this peridotite body that primarily consisted of olivine and pyroxene was later serpentinized. Because of significant differences in Mount Alberts topography, the history of this alteration process could be described to some extent by means of three-dimensional trend analysis.

Using other examples, it was shown that the residuals from trend surfaces generally are not stochastically independent but autocorrelated. The methods of time series analysis and geostatistics then can be used to extract meaningful patterns superimposed on the trend surfaces.

Biography

Professor John Wilder Tukey (1915–2000) was born in New Bedford, Massachusetts. As a student at Brown University, he took a course in geology, a subject in which he remained interested during his long and distinguished career. In 1965, he became the founding chairman of the Department of Statistics at Princeton University where he had obtained his PhD in 1939. He also was a director at the AT&T Bell Laboratories. Among his many honors, there was the 1982 Medal of Honor of the Institute of Electrical and Electronics Engineers received for his contributions to spectral analysis of random processes (cf. Blackman and Tukey 1958) and inventing the FFT (Fast Fourier Transform) (cf. Cooley and Tukey 1965). Tukey is probably best known for his book on *“Exploratory Data Analysis”* (Tukey 1977). He added words to the English language: “bit” (in 1947) and “software” (in 1958). At the 53rd Session of the International Statistical Institute (ISI) held in Seoul, Korea (in 2001), John Tukey was declared to be one of the most prominent mathematical statisticians during the second half of the twentieth century.

Tukey has produced over 800 publications. His impact in the field of mathematical geoscience included collaborations with geoscientists. With Bill Krumbein, he worked on multivariate analysis of mineralogical, lithological, and chemical rock composition data (Krumbein and Tukey 1956). Personally, I have had the privilege of working with Tukey on four occasions. In 1966, when I was “petrological statistician” at the Geological of Canada in Ottawa, I participated in an advanced statistical seminar organized by George E.P. Box at the University of Wisconsin. Tukey approached me and subsequently arranged that I received a box with about 2,000 IBM cards to calculate the FFT in one-, two-, or three dimensions on a mainframe computer.

Tukey (1970) was the discussant of a paper I presented at a “Geostatistics” symposium held at the Geological Survey of Kansas. In it, I had divided a map area into three parts. Observations from two parts were used to make predictions in the third, “blind” map area. Tukey pointed out that this form of cross-validation could indeed be used, but a better technique would be to use the jackknife method proposed by Mosteller and Tukey (1968). I also discussed applications of autocorrelation and spectral analysis. According to Tukey, spectra are better. With respect to one example, he pointed out that, although the signal-plus-noise model results for it were within the 95% confidence limits, only the spectrum showed that this approach was not fully satisfactory. It is remarkable that much later, in an application of their universal multifractal method to the same data set, Lovejoy and Schertzer (2007, Fig. 26a) provided a spectrum that perfectly described the lack of fit originally noticed by Tukey.

At the 38th ISI meeting held in Washington, D.C., I presented a paper on mineral potential maps useful to predict the probable occurrences of unknown large copper and zinc deposits. Lithological and geophysical variables quantified for (10 x 10 km) cells were used as explanatory variables in multiple regressions to estimate probabilities of occurrence. Tukey (1972) who was the discussant of this paper pointed out that it might be better to estimate probabilities confined to the [0,1] interval by using logistic analysis. Subsequently, my colleagues and I, in the Geomathematics Section of the Geological Survey of Canada, extensively used logits in similar studies, e.g., in weights of evidence (WofE) modeling. Later, Tukey (1984) commented again on mineral potential maps correctly pointing out that the probabilities of finding new ore deposits were greater on the flanks than on the maxima on these contour maps.

Turbulence

Frits Agterberg
Central Canada Division, Geomathematics Section,
Geological Survey of Canada, Ottawa, ON, Canada

Definition

Turbulence is the motion of a fluid or gas that is characterized by chaotic changes in pressure as well as in flow or stream velocity. It is created in fluid flow when the kinetic energy

exceeds the damping effect of the fluid's viscosity. Most atmospheric air circulation is affected by turbulence and so are strong oceanic currents and fast-flowing rivers. When river flow is slow, the water moves slowly around obstacles without turbulence but, when flow exceeds a specific limit, turbulence is generated. This critical velocity is characterized by its Reynolds number usually written as R . Sommerfeld (1908) pointed out that the first value of R was established in 1883 by Osborne Reynolds who performed a number of flow visualization experiments in a pipe. A major breakthrough in the understanding of turbulence came with the publication of Kolmogorov (1941)'s similarity principle for R showing that it is the only control parameter for incompressible flow. This principle eventually led to the theory of multifractals anticipated by Mandelbrot (1989) and later firmly established by many authors including Frisch (1995) and Sreenivasan (1991). In respect to the past, the geologic record contains Bouma sequences in sedimentary basins of different ages proving continuous past existence of turbulence in the form of turbidity currents.

Introduction

According to the so-called Orr-Sommerfeld equation:

$$R = \frac{L \cdot V}{\nu}$$

where L is a measure of scale, V represents the fluid's velocity and ν is the kinematic velocity (cf. Frisch 1995). The similarity principle for incompressible flow states that, for a given geometrical shape of the boundaries, the Reynolds number is the only control parameter of the flow.

Applications of the theory of turbulence in geosciences are concerned with movements of air in the atmosphere and with water in oceans, lakes, and rivers. Also, evidence of turbulence resulting in turbidity currents that took place millions of years ago has been found in the bedrock of different geologic ages and has become part of the geologic record. There also exists evidence of turbulence in the past that was connected to the rapid movement of solid matter on land in connection with earthquakes and landslides.

Lee (2013) has characterized turbulence stability through the identification of multifractional Brownian motions (mBm) that constitute a generalization of the fractional Brownian motion concept (fBm). Such models represent mBm as a Gaussian process $W(t)$ with a time-dependent function $H(t)$ replacing the Hurst exponent H . Its variance at time t is assumed to be $\text{Var}[W(t)] = C^2 t^{H(t)}$ with the constant C determining the energy level of the process. It has been shown that atmospheric turbulence is anisotropic requiring different scaling exponents related to the Hurst exponent

(Lovejoy et al. 2010). Lee (2013) separately identified atmospheric turbulence signals for longitudinal, lateral, and vertical velocities as well as for temperature.

Turbidity Currents

Turbulence was involved in turbidity currents that resulted in the rapid deposition of sediments. A simple form of turbidity current occurred during the Quaternary retreat of land-ice that resulted in varves consisting of couplets of thin silt and clay layers. The varves were deposited annually in lakes formed in front of the retreating masses of land-ice. Instantaneous silt formation due to turbidity currents in the summer was followed by slow clay deposition during the remainder of the year as originally shown by Kuenen (1951). Older sedimentary rocks often show so-called Bouma sequences, which are the fossilized remains of turbidity currents in basins that existed at different times during the history of the Earth.

Emplacement of massive turbidites linked to the extinction of turbulence in turbidity currents often resulted in complete or partial manifestations of Bouma sequences (Cantero et al. 2011). A complete Bouma (1962) sequence consists of five distinct layers of sedimentary rocks with specific lithologies. In a fully preserved Bouma sequence, these are, from bottom to top: (1) massive to coarse-grained sandstone, often with pebbles; (2) medium- to fine-grained sandstone, frequently with sole markings such as flute casts indicating the direction of turbidity flow; (3) fine-grained sandstone with ripple marks; (4) parallel-laminated siltstone; and (5) mudstone, possible with trace fossils. Of course, there was no preservation of any water above, within and below any Bouma sequence when it was created.

Various quantitative models have been developed to explain Bouma sequences that can be of any geologic age and which commonly show lateral variations of composition in the flow direction. One such quantitative model is Parker (2008)'s "Turbidity Current with a Roof" (TCR) model of flow driven by suspended sediment within a layer of thickness H , which is confined between two parallel plates with standing water below and above it. Suppose that ρ represents water density, ρ_s is sediment density, s represents channel slope, and ν is the kinematic viscosity of water. According to Cantero et al. (2011), the turbulence for the TCR model then is controlled by the following three dimensionless parameters: the shear Richardson number R_1 , shear Reynolds number R_2 and fall velocity $\hat{V}$. The first two of these parameters satisfy:

$$R_1 = \frac{RgCH}{2u^2}; R_2 = \frac{uH}{2\nu}$$

where $R = \frac{\rho_s}{\rho} - 1$ (≈ 1.65 for quartz), g is the gravitational acceleration, C is the layer-averaged volume suspended sediment concentration, and u is nominal shear velocity. The dimensionless fall velocity is

$$\hat{V} = \frac{V_s}{u}$$

where V_s is the sediment fall velocity. The preceding equations provide only a partial explanation of this version of the TCR model. A complete explanation with graphical illustrations is provided in Cantero et al. (2011).

Summary and Conclusions

Turbulence occurs when fluid or air movement exceeds a critical value characterized by a Reynolds number R . It occurs in the atmosphere, rivers, and oceans. Kolmogorov (1941) established the similarity principle for R stating that it is the only control parameter for incompressible flow. This concept has resulted in the theory of multifractals. Various theoretical models continue to be developed for turbulence with parameters that change in space and time. The geologic record contains Bouma sequences in sedimentary basins of different ages proving the past existence of turbulence in the form of turbidity currents.

Biography

Donald L. Turcotte is recognized globally for his quantification of nearly all aspects of physical geology.

Professor Turcotte received a Ph.D. in aeronautics and physics from the California Institute of Technology in 1958. After a year at the Naval Postgraduate School in Monterey, he joined the Graduate School of Aeronautical Engineering at Cornell where he addressed seeded combustion, magnetohydrodynamic phenomenon in turbulent boundary layers, and shock waves. He became Full Professor and published his first two books: *Space Propulsion and Statistical Thermodynamics* and *Statistical Thermodynamics*.

Professor Turcotte became an earth scientist in 1965 when he went on sabbatical to Oxford University and met Ron Oxburgh. His quantitative abilities and physical intuition combined with Ron's knowledge of geology to produce

24 papers that quantified the emerging paradigm of plate tectonics, establishing the physical basis of processes in the Earth's thermal boundary layer, ridge melting, subduction zone volcanism, and intraplate tectonics and magmatism. In 1973, he left the School of Aeronautical Engineering and joined the Cornell Department of Geological Sciences where he became an expert on planetary remote sensing, thermal subsidence in sedimentary basins, two-phase hydrothermal porous media convection, lithosphere flexure, cyclic sedimentation, stick-slip earthquakes, and the lithospheres and mantles of the other planets. In 1982, he and Jerry Schubert published *Geodynamics*, which remains the primary reference book quantifying physical earth processes.

In 1985, Bob Smalley introduced Professor Turcotte to fractals. This became his next fascination, perhaps because fractals and chaos apply to almost every Earth process, explaining, at last, why geologists must always place their rock hammers in their photographs to establish scale. In 1992, he published *Fractals and Chaos in Geology and Geophysics*, a primary reference in this new field.

Professor Turcotte is renowned for his productivity, ability to inspire and collaborate, his administrative skills, and pleasant equanimity. He has published over 300 papers in refereed journals and authored or coauthored 4 books, most recently a comprehensive 2001 treatise on mantle convection with Jerry Schubert and Peter Olson. As a member of innumerable academy committees, editorial boards, working groups, past president of the Tectonics Section of the AGU, chair of the Geophysics Section of the National Academy of Sciences, and chair of the Department of Geology at Cornell for 9 years, he has interacted with nearly everyone in the geophysics profession, all of whom appreciate his remarkable ability to routinely turn mountains into molehills.

Professor Turcotte has been recognized by election to the National Academy of Sciences, receipt of the Arthur L. Day medal of the Geological Society of America, the Charles A. Whitten Medal, and the William Bowie Medal of the American Geophysical Union. The Bowie Medal is the AGU's most prestigious award and honors "outstanding contributions to fundamental geophysics and unselfish collaboration in research," which fits Don perfectly.

Unbalanced Analysis of Variance

R. Webster

Rothamsted Research, Harpenden, UK

Definition

The analysis of variance is a statistical technique, or set of techniques, for separating variance in data into portions that can be attributed to two or more sources of variation. The form of an analysis must fit the experimental or survey design by which the data were obtained. Balanced designs are ones in which all sources at any particular level of classification are observed equally. In the geosciences balance is exceptional; it is rarely possible or even undesirable to measure the same number units in all classes of rock or soil in a region. Data from surveys are almost always unbalanced, either because of circumstances or by deliberate design. The corresponding analyses of such data are therefore also unbalanced. Unbalanced nested designs are especially important in regional geochemistry.

Introduction

In the 1920s RA Fisher set out the principles of experimental design whereby investigators could distinguish effects of their experimental treatments from natural variation in the material being investigated. These comprised replication, to provide information on the variation in responses to the treatments, and randomization to avoid bias that could arise if effects of treatments were confounded with other sources of variation. Fisher devised the analysis of variance (ANOVA) to separate the sources of variation in data from such experiments, to estimate quantitatively the effects of the treatments and to provide inferential tests to judge whether the observed differences could properly be attributed to the imposed treat-

ments rather than their arising by chance. Fisher's innovation was a revolution in agronomy, and it was quickly followed in biological and medical research, and it has been subsequently embraced by geoscientists for surveys in which the same principles apply.

Single-Stage Analysis of Variance

Balanced Designs

Fisher was initially concerned with fertilizer experiments in the field. Treatments were assigned to plots at random, and all treatments would be replicated equally; in other words, the design was *balanced*. For generality we can designate the treatments as "classes." In the simplest cases there is only one level of classification, and the design can be summarized in a single-stage ANOVA table, such as Table 1.

The quantity σ_B^2 , the variance between classes, arises from the differences among the class means. It is a fixed effect determined by the investigator. The quantity σ_W^2 is the within-classes variance, a random quantity estimated by W . It determines the confidence one can have in the class means and any differences between them. The variance of a class mean, say $\bar{z}_{\text{class}}$, would be W/n and its standard error $\sqrt{W/n}$. Agronomists are typically concerned with differences between treatments and compute the standard error of any difference, say $\bar{z}_1 - \bar{z}_2$, as

$$\text{SED} = \sqrt{2W/n}. \quad (1)$$

Unbalanced Design

The same principles apply to surveys. Surveyors, however, rarely have complete control over replication and often do not want it. A geoscientist might sample the soil of a region to estimate the concentration of some element or pollutant in the soil. Different concentrations in soil derived from different classes of parent rock or under different forms of land management would express themselves in the between-classes

Unbalanced Analysis of Variance, Table 1 Analysis of variance for a single-stage balanced completely randomized design with k classes, each replicated n times

Source	Degrees of freedom	Mean square	Parameters estimated	F ratio
Between classes	$k - 1$	B	$\sigma_W^2 + n\sigma_B^2$	B/W
Within classes (residual)	$k(n - 1)$	W	σ_W^2	
Total	$kn - 1$	T		

Unbalanced Analysis of Variance, Table 2 Analysis of variance for a single-stage unbalanced completely randomized design with k classes, replicated $n_1, n_2, \dots, n_k$ times to give N observations in total

Source	Degrees of freedom	Mean square	Parameters estimated	F ratio
Between classes	$k - 1$	B	$\sigma_W^2 + n_0\sigma_B^2$	B/W
Within classes (residual)	$N - k$	W	σ_W^2	
Total	$N - 1$	T		

variance. It is highly unlikely that all classes of rock or land management would be represented equally; the design would be *unbalanced*. Nevertheless, with only one level of classification the ANOVA is still fairly straightforward. Table 1 is replaced by a somewhat more elaborate Table 2.

The contribution of the between-classes variance, σ_B^2 , to the mean square B is somewhat modified. The quantity n of Table 1 is replaced by n_0 given by

$$n_0 = \frac{1}{k-1} \left(N - \frac{\sum_{i=1}^k n_i^2}{N} \right). \quad (2)$$

In an investigation intended to determine the means of each class the differences among the classes comprise a fixed effect, as in the experimental situation. More often in surveys the classes are not predetermined, and the differences among classes arise by chance; they are random effects. In these circumstances σ_B^2 is of interest in its own right and is known as a component of variance.

Further, each class mean $\bar{z}_i$ has its own unique variance estimated by W/n_i and standard error $\sqrt{W/n_i}$ that depend on the number of observations contributing to the mean. The standard error of a difference between two classes, say class 1 and class 2, is

$$\text{SED} = \sqrt{W \left(\frac{1}{n_1} + \frac{1}{n_2} \right)}. \quad (3)$$

Geoscientists are less likely to be interested in the differences between class means than agronomists would be. Nevertheless, Eq. (3) provides the SED.

The simplest of designs represented by Table 1 could be elaborated by blocking, by factorial combinations of treatments, by splitting the plots, and by nesting the treatments one within another; see, for example, Cochran and Cox (1957). Balance would be retained provided that the replication was equal at any level in the design. Balance could be upset if lack of experimental resources or partial failure in an experiment meant that replications were unequal; the analysis would then have to take the lack of balance into account. The most general means for this is by residual maximum likelihood (REML) proposed by Patterson and Thompson (1971), and facilities for it are now available in statistical packages.

Multi-stage Analysis of Variance

The classes of land encountered in surveys are often nested one within another. For example, an agricultural region may comprise administrative districts (stage 1), each divided into farms (stage 2), which in turn are divided into fields (stage 3), and the soil of each of field is sampled at several places (stage 4) to provide the observations. In each case the class at the lower stage is contained completely within the one immediately above it, and each sampling point is contained in one and only one class at each and every stage. The system is a strict hierarchy, a nested structure, and a single observation embodies variation contributed by all of the stages, including an unresolved variance within the classes at the lowest level. The system can be modeled as

$$Z_{ijkl} = \mu + A_i + B_{ij} + C_{ijk} + \varepsilon_{ijkl}. \quad (4)$$

Here Z_{ijkl} is the value of the l th observation of the k th class at stage 3, in the j th class at stage 2, and in the i th class at stage 1. The general mean is μ ; A_i is the difference between μ and the mean of class i in the first stage; B_{ij} is the difference between the mean of the j th sub-class in class i and the mean of class i ; and so on. The final quantity ε_{ijkl} represents the deviation of the observed value from its class mean in stage 3. More stages can be added as desired.

Balanced Designs

A hierarchical design is balanced if all classes at each particular stage are represented equally. The ANOVA table would then appear as Table 3, for which analysis itself is straightforward.

The variance of a mean at any one stage in the design is obtained as the mean square within that stage divided by the number of observations contributing to that mean. If we denote the estimates of the variance components by $s^2 = \hat{\sigma}^2$ then the estimation variances are

Unbalanced Analysis of Variance, Table 3 Analysis of variance for a three-stage balanced completely randomized design with n_1 classes at stage 1, n_2 in each class at stage 2, n_3 in each class at stage 3, and n_4

observations in each class at stage 3 to give $N = n_1 n_2 n_3 n_4$ observations in total and variance parameters

Source	Degrees of freedom	Mean square
Stage 1	$n_1 - 1$	$\frac{1}{n_1 - 1} \sum_{i=1}^{n_1} n_4 n_3 n_2 (\bar{z}_i - \bar{z})^2$
Stage 2	$n_1(n_2 - 1)$	$\frac{1}{n_1(n_2 - 1)} \sum_{i=1}^{n_1} \sum_{j=1}^{n_2} n_4 n_3 (\bar{z}_{ij} - \bar{z}_i)^2$
Stage 3	$n_1 n_2(n_3 - 1)$	$\frac{1}{n_1 n_2(n_3 - 1)} \sum_{i=1}^{n_1} \sum_{j=1}^{n_2} \sum_{k=1}^{n_3} n_4 (\bar{z}_{ijk} - \bar{z}_{ij})^2$
Residual	$n_1 n_2 n_3(n_4 - 1)$	$\frac{1}{n_1 n_2 n_3(n_4 - 1)} \sum_{i=1}^{n_1} \sum_{j=1}^{n_2} \sum_{k=1}^{n_3} \sum_{l=1}^{n_4} (\bar{z}_{ijkl} - \bar{z}_{ijk})^2$
Total	$N - 1$	$\frac{1}{N - 1} \sum_{l=1}^N (z_l - \bar{z})^2$
Parameters estimated by mean squares		
Stage 1	$n_1 - 1$	$n_4 n_3 n_2 \sigma_1^2 + n_3 n_2 \sigma_2^2 + n_2 \sigma_3^2 + \sigma_4^2$
Stage 2	$n_1(n_2 - 1)$	$n_3 n_2 \sigma_2^2 + n_2 \sigma_3^2 + \sigma_4^2$
Stage 3	$n_1 n_2(n_3 - 1)$	$n_2 \sigma_3^2 + \sigma_4^2$
Residual (stage 4)	$n_1 n_2 n_3(n_4 - 1)$	σ_4^2
Total	$N - 1$	

The quantities $\bar{z}_i$, $\bar{z}_{ij}$, $\bar{z}_{ijk}$, and $\bar{z}_{ijkl}$ are the means of observations at the four levels of the design

$$\begin{aligned} s^2(\bar{z}_3) &= s_4^2/n_4 \\ s^2(\bar{z}_2) &= s_4^2/(n_4 n_3) + s_3^2/n_3 \\ \text{and } s^2(\bar{z}_1) &= s_4^2/(n_4 n_3 n_2) + s_3^2/(n_3 n_2) + s_2^2/n_1. \end{aligned}$$

If the classes at the several stages can be regarded as random then the corresponding variances σ_1^2 , σ_2^2 , σ_3^2 , and σ_4^2 are components of variance like σ_B^2 above.

Unbalanced Designs: Multi-stage Survey and the Variogram

One particular form of multi-stage design that is finding increasing application in the geosciences and environmental science more widely is one in which the classes are specific distances between sampling points in surveys. Pairs of points, or perhaps sets of three points, are spaced at some fixed distance but in a random orientation from one another; these pairs or triplets are grouped with other pairs or triplets some larger fixed distance apart but again in a random direction; those in turn are grouped with yet other groups a further fixed distance apart, and so on. The structure is spatially nested. The distances typically increase in at least 2.5-fold progression so that the nests at any one stage never overlap in space and are reasonably independent. The design enables one to estimate the contributions of differences at these distances to the total variance from an ANOVA as set out in Table 3. It reveals which spatial scales contribute to the variance and how to plan future surveys efficiently. The procedure was first proposed with that aim by Youden and Mehlich (1937), but it lay dormant until the 1970s.

Miesch (1975) described it in a geochemical setting and linked it to the variogram of geostatistics. He pointed out that if the components of variance were accumulated, starting with the smallest spacing, they formed an estimate of the variogram. For m stages of nesting at distances d_m , d_{m-1} ,

..., d_1 , where d_m is the shortest distance at the m th stage and m_1 is the distance at the first stage, the equivalences are

$$\begin{aligned} \hat{\sigma}_m^2 &= \hat{\gamma}(d_m), \\ \hat{\sigma}_{m-1}^2 + \hat{\sigma}_m^2 &= \hat{\gamma}(d_{m-1}), \\ \hat{\sigma}_{m-2}^2 + \hat{\sigma}_{m-1}^2 + \hat{\sigma}_m^2 &= \hat{\gamma}(d_{m-2}), \end{aligned} \quad (5)$$

and so on.

The scheme is elegant, but to maintain balance the number of sampling points would have to double or triple at each additional stage in the design; the sampling would increase exponentially as the number of stages, that is, distances, increases; it would soon become unaffordable. To make it affordable balance must be sacrificed; only some of the nests in the lower stages contain replicates. The ANOVA is more complex than in the balanced design. The sums of squares are formed in the same way by the method of moments, but the degrees of freedom vary according to the precise structure of the replication in each stage. Further, and more important for a first estimate of a variogram, the coefficients by which the components of variance are multiplied vary from stage to stage. Table 4 sets out the ANOVA for three stages of classification.

The coefficients u can be calculated by the formulae originally provided by Gower (1962):

$$q_{i,j} = \sum_{k=1}^{C_i} \sum_{p=1}^{C_{jk}} \frac{n_{pj}^2}{n_{ik}} \quad \text{and} \quad u_{i,j} = \frac{1}{D_i} (q_{i,j} - q_{i-1,j}). \quad (6)$$

The quantities in the formulae are as follows:

$u_{i,j}$ is the coefficient at stage i for the j th component, C_i is the number of classes at stage i ,

C_{jk}^i is the number of sub-classes in stage j within the k th class in stage i ,
 n_{pj} is the number of sampling points in the p th sub-class at stage j (within class k at stage i) with $i \leq j$, and
 D_i is the number of degrees of freedom at stage i .

Illustrative Example: Lead in the Soil of the Jura

A geochemical survey of potentially toxic metals in the topsoil of the Swiss Jura by Atteia et al. (1994) illustrates the technique. Its aim was to discover the spatial scale(s) of variation and where large concentrations of metals posed a risk to health. A region of 14.5 km² was sampled at 214 nodes of a square grid at 250-m intervals. Thirty eight of the nodes were chosen at random as starting points for nested sampling with four additional stages, only the last of which was replicated two-fold. The design was highly unbalanced. Table 5 sets out the ANOVA for lead (Pb), for which the mean concentration of 57 mg kg⁻¹ exceeded the statutory threshold of 50 mg kg⁻¹ and concentrations were much more in excess locally.

Note that there is a substantial contribution at 15 m and relatively little between 15 and 250 m. The estimated component at 40 m is very small and may be regarded as an estimate of zero. The accumulated components form a rough variogram. Atteia et al. went on to plot the accumulated components on a variogram computed for lag distance increasing in equal increments.

Unbalanced Analysis of Variance, Table 4 Analysis of variance for a three-stage unbalanced completely randomized design

Source	Degrees of freedom	Parameters estimated by mean squares
Stage 1	$D_1 = f_1 - 1$	$u_{1,1}\sigma_1^2 + u_{1,2}\sigma_2^2 + u_{1,3}\sigma_3^2 + \sigma_4^2$
Stage 2	$D_2 = f_2 - f_1$	$u_{2,2}\sigma_2^2 + u_{2,3}\sigma_3^2 + \sigma_4^2$
Stage 3	$D_3 = f_3 - f_2$	$u_{3,3}\sigma_3^2 + \sigma_4^2$
Residual (stage 4)	$D_4 = N - f_3$	σ_4^2
Total	$N - 1$	

Residual Maximum Likelihood Estimation

The ANOVAS as set out in Tables 4 and 5 for unbalanced sampling are sound. The estimates of the variance components are unbiased, though statisticians now prefer residual maximum likelihood (REML) for estimating them. Webster et al. (2006) and Webster and Lark (2013) provide the detail. For balanced designs the results of ANOVA and REML are the same; for unbalanced designs REML estimates of the components of variance differ somewhat from those computed with Gower's coefficients. The right-hand column of Table 5 lists the components of variance as estimated by REML for comparison.

Many other experimental and survey designs may be unbalanced, either by intention for economy, or by chance, or by unforeseen circumstances such as loss of data, failure of instruments, or no access to land. The REML technique, with its great flexibility, will usually enable investigators to cope with the lack of balance whereas ANOVA might not.

Summary

The analysis of variance (ANOVA) devised originally for estimating the effects of imposed treatments in field experiments is readily adapted to surveys provided sampling has been suitably randomized. Whereas experimental treatments can be replicated equally so that designs are balanced, equal replication of classes in survey is exceptional and frequently undesirable. Survey designs are usually unbalanced, and the ANOVAS, which must fit the designs, are unbalanced. Geochemists have a particular interest in nested sampling designs for discovering the spatial scales of ores, metals, and pollutants. The designs are almost necessarily unbalanced for economy. The ANOVAS for such designs are tabulated, and the formulae for computing the components of variance are given. The analysis for a highly unbalanced nested sample survey is illustrated with data on lead (Pb) in the soil from a geochemical survey in the Swiss Jura. The components of variance are estimated by a hierarchical analysis of variance and compared with ones estimated by the now favored residual maximum likelihood.

Unbalanced Analysis of Variance, Table 5 Unbalanced analysis of variance for the concentration of lead in the soil of the Swiss Jura

Source (Distance)	Degrees of freedom ^a	Mean square	Variance component	Cumulative variance	REML estimate
Stage 1 (>250 m)	211	2047	590.2	1532.2	402.7
Stage 2 (100 m)	38	1082	154.0	942.0	282.4
Stage 3 (40 m)	37	856	3.6	788.0	7.0
Stage 4 (15 m)	38	937	458.8	784.4	483.2
Stage 5 (6 m)	38	326	325.6	325.6	277.2
Total	362	1528			

The measurements were in mg kg⁻¹

^aThere were three missing values; the total degrees of freedom are therefore 362 for 363 data from the 366 sampling points

Definition

An issue in all geochemical anomaly classification methods is uncertainty in the identification of different populations and allocation of samples to those populations, including the critical category of geochemical anomalies or patterns that are associated with the effects of mineralization. This is a major challenge where the effects of mineralization are subtle.

Introduction

There are various possible sources of such uncertainty, including (i) gaps in coverage of geochemical sampling within a study area; (ii) errors in geochemical data analysis, spatial measurement, interpolation; (iii) misunderstanding of geological and geochemical processes; (iv) fuzziness or vagueness of the threshold between geochemical background and geochemical anomalies; and (v) errors associated with instrument measurement and the associated calibration, in

particular errors associated with accuracy and errors associated with precision (Costa and Koppe 1999; Lima et al. 2003; Walker et al. 2003; Bárdossy and Fodor 2004; McCuaig et al. 2007, 2009, 2010; Kreuzer et al. 2008; Kiureghian and Ditlevsen 2009; Singer 2010; Singer and Menzie 2010; Caers 2011; Zuo et al. 2015). However, there are further potential biases induced by data closure effects in compositional data, which may be dealt with by the use of ratios for which a number of methods exist on the basis of Aitchison geometry (Filzmoser et al. 2009; Carranza 2011; Pawlowsky-Glahn and Buccianti 2011; Gallo and Buccianti 2013; Buccianti and Grunsky 2014; Sagar et al. 2018; Zuzolo et al. 2018; Pospiech et al. 2020). The use of appropriate log-ratio transformations, including clr and ilr – see the ► “Compositional Data” entry – is adequate to represent the data in real coordinates, necessary for a proper modeling and outlier detection.

Such issues generate two main types of uncertainty in geochemical anomaly recognition and mapping that are (i) stochastic uncertainty related to the quality and variability of geochemical data, which affects the results of methods and (ii) systematic uncertainty associated with assumptions and procedures for collection, analysis, and modeling of geochemical data (Porwal et al. 2003; Zuo et al. 2015). Due to analytical and interpolation errors in unsampled or under-sampled areas, there will be both stochastic uncertainty and procedural systematic uncertainty in thresholds achieved from geochemical anomaly classification models. Mathematical uncertainties inherent within the different threshold-determining methods defined can easily be quantified using existing statistical measures.

Geospatial interpolation by any method is one of the main sources of uncertainty in continuous field geochemical models (Costa and Koppe 1999). However, errors in the characterization of significant geochemical anomalies are not only due to interpolation errors in sampled/unsampled areas. Error propagation analysis should be considered and can be assessed using methods such as Monte Carlo simulation.

Error propagation from data collection to data analysis results in thresholds to populations spanning a range of values with the relative magnitude of such ranges dependent on the magnitude of sampling, analytical and interpolation errors (Stanley 2003; Stanley and Lawie 2007; Stanley et al. 2010). In effect, every estimate of a geochemical value in a continuous field model represents a range of values due to statistical and interpolation errors. However, existing methods of geochemical anomaly recognition do not consider error propagation and stochastic and systematic uncertainty quantification in the analysis. Additionally, existing methods assume in general errors to be additive, what is clearly not appropriate with compositional data. This, in turn, results in uncertainty whether observed geochemical anomalous samples or populations are statistically significant.

Uncertainty in Geochemical Anomaly Classification Models

A variety of geostatistical and other mathematical methods have been applied to classify or cluster regolith geochemical data. A common objective is to define clusters that can be spatially related to mineralization, based on univariate or multivariate characteristics. Given the range of factors that can affect regolith geochemistry, including variations in parent lithology, regolith processes, and climatic effects, all such methods are subject to uncertainty in sample classification and pattern recognition, and identification of samples which geochemistry has (or has not) been affected by mineralization (i.e., a geochemical anomaly). This affects stochastic geochemical classification methods including fractal-based models.

Uncertainties associated with geochemical data collection and data analysis can result in two types of errors (Koch and Link, 1970) in relation to the null hypothesis connecting detection or lack of detection of a geochemical anomaly with the associated presence or absence of mineralization. As with all such statistical tests, a Type I error or false positive occurs when the null hypothesis is rejected when the proposition is true, and a Type II error or false negative occurs when the null hypothesis is false but is accepted. From geochemical exploration point of view (Table 1), a Type I error occurs when an ore deposit exists in an area, but no mineralization is detected on the classified map; and a Type II error occurs in an area where there is no deposit but has been classified as an anomalous area. Type I errors preclude mineral discovery, whereas Type II errors will entail exploration expenditure that does not result in mineral discovery. Both types of errors have economic consequences (Rose et al. 1979; Table 1), hence there is a need to be able to quantify the overall accuracy (OA) of the geochemical population characterization as represented by the OA matrix contingency table of Carranza (2011) set out in Table 2.

This ideal approach is, however, flawed as neither b or d can be determined due to the inability in many cases to determine whether undetected mineralization is actually

present in an area where the geology would permit the presence of such mineralization (Yilmaz et al. 2017). It is only possible to experimentally gauge the OA in terms of the geochemical response to known mineralization, hence the typical design of most geochemical orientation surveys that focus on patterns associated with known mineralization and commonly provide insufficient assessment of pattern variations away from the direct influence of mineralization. A partial overall accuracy (POA) contingency table is therefore defined as:

$$POA = a/(a + c) \quad (1)$$

In geochemical exploration projects or orientation studies, the number of samples collected is always limited due to budgetary and other constraints. Therefore, in order to define and predict the spatial mineralization patterns using the available samples in sampled and unsampled areas, interpolation of the available data values is required to assign estimated values to unsampled areas (Chilès and Delfiner 2012; Sadeghi et al. 2015).

Interpolation using any single method is one of the main sources of uncertainty in continuous field geochemical models as interpolation estimates are based only on data within the search window (Costa and Koppe, 1999). In order to evaluate the effect of interpolation errors in detecting geochemically anomalous populations, error propagation should be analyzed (Bedford and Cooke 2001; Oberkampff et al. 2002, 2004; Stanley 2003; Helton et al. 2004; Stanley and Lawie 2007; Verly et al. 2008; Stanley et al. 2010; Mert et al. 2016; Sagar et al. 2018).

Monte Carlo Simulation (MCSIM) to Quantify Systematic Uncertainty

One significant method for analyzing the propagation of error in models and evaluating their stability is the Monte Carlo simulation (MCSIM) (Taylor 1982; Heuvelink et al. 1989). The MCSIM is a computational algorithm that generates random numbers or realizations given a specific density function (Pyrcz and Deutsch 2014; Pakyuz-Charrier et al. 2018; Athens and Caers 2019; Madani and Sadeghi 2019), derived from various parameters controlling that probability density function or the cumulative equivalent (the PDF or CDF) as shown in Fig. 1 (Deutsch and Journel 1998; Scheidt et al. 2018). As the MCSIM is based on the PDF and CDF evaluations, it can be applied to high-dimensional and nonlinear spatial modeling approaches to determine the probability of the target mineralization values occurrence based on the probability distributions relating to a given model (Athens and Caers 2019).

Uncertainty Quantification, Table 1 Classification of samples versus real condition

		Reality	
		Ore present	Ore not present
Assigned class	Anomalous	Correct decision	Type II error – wasted exploration expenditure
	Background	Type I error – mineralization not detected	Correct decision

Adapted from Rose et al. (1979)

Uncertainty Quantification, Table 2 Overall accuracy (OA) matrix to compare performance of a binary model geochemical anomaly or signal recognition with binary ground truth (Sadeghi 2020)

		Geological ground truth	
		Mineralization present and affecting sample geochemistry	No mineralization present
Classification of sample (or pixel)	Anomalous	True anomaly = a	False anomaly = b
	Background	False background = c	True background = d
		Type I error =	$c/(a + b + c + d)$
		Type II error =	$b/(a + b + c + d)$
		Overall accuracy (OA) =	$(a + d)/(a + b + c + d)$

**Uncertainty Quantification, Fig. 1** Schematic PDF and CDF plots and associated quantiles (in this case the P10, P50, and P90 values). (Sadeghi 2020; modified from Scheidt et al. 2018)

Under the MCSIM approach, the P50 (median) value (the average 50th percentile of the multiple simulated distributions) represents a neutral probability in decision-making (Scheidt et al. 2018), and is defined as the expected “return.” The uncertainty is calculated, in this approach, as $1/(P90-P10)$ for which P10 (lower decile) and P90 (upper decile) are the average tenth and 90th percentiles of the multiple simulated values (Caers 2011; Scheidt et al. 2018), associated with each element.

The implications of the MCSIM modeling mainly relate to sampling density (though may also relate to sample data quality if that can be disentangled from natural geochemical variability). In the recognition of geochemical processes, the sampling density reflects processes that can be adequately represented or processes that are under-represented. Under-represented processes can appear as noise and is apparent when multivariate methods such as principal components are applied to the data (Grunsky and Kjarsgaard 2016). Typically, under-represented processes occur in such methods that are defined by the smaller eigenvalues. Where the quantified return is low or negative, and the quantified uncertainty is high, especially higher than its related return, a decision may be made that additional sampling is required to achieve the minimum required spatial continuity in the data or the stability of the fractal models (Fig. 2). If it goes uncertain, the final models and related classes would not be certain enough, which affects the entire certainty of the models generated in the whole study area.

Spatial Uncertainty

The systematic uncertainty of the thresholds or classes obtained by each classification model was discussed above. However, there is another type of uncertainty that is related to the final maps generated by interpolation of the available values in the sampled areas and assignment of interpolated values to unsampled areas. A single interpolated map has unknown precision (stability) and accuracy. The precision can be estimated by application of simulation methods, such as sequential Gaussian simulation (SGSIM), with a large number of realizations (simulated maps) – see the ► “Simulation” entry. Such simulation models are mostly based on kriging interpolation methods (e.g., ordinary kriging and regression kriging) that minimize or compensate for precision issues.

The difference or dissimilarity between realizations provides the estimate spatial uncertainty of the simulated models. Based on the initial and estimated values in a frequency framework, and the spatial uncertainty obtained using several realizations simulated in a Bayesian framework, areas for targeting are those with highest concentration frequency and lowest spatial uncertainty. The principal target areas for the follow-up exploration are those displaying strongly anomalous or very strongly anomalous populations. For such evaluations and to apply the established simulation algorithms, the rasterized (regular or Cartesian) grids are not required as

Uncertainty Quantification, Fig. 2 Schematic of Monte Carlo uncertainty propagation and decision-making workflow applicable to any classification model (Sadeghi 2020)

well, so they are applied to irregular grids such as point-sets (Remy et al. 2009).

The realizations are often complex and of high dimensionality, hence representing them mathematically in extremely high-dimensional Cartesian space is not feasible. As an alternative to focusing on the realizations themselves, the differences between realizations can be analyzed. To achieve this, the concept of the “distance” has been proposed by Scheidt and Caers (2008, 2009). Conceptually, the distance is a single positive value quantifying the total difference between the outputs from any two realizations (Caers 2011; Scheidt et al. 2018). The average distances or variability between realizations (similar to the standard error of the mean) can also be determined.

Based on the data types and the associated parameters, various metrics have been developed to quantify the distance between two realizations, such as the Hausdorff distance (Suzuki and Caers 2006), time-of-flight-based distances (Park and Caers 2007), and flow-based distance using fast flow simulators (Scheidt and Caers 2008). The simplest distance calculation in 2D models for non-dynamic data such as regolith geochemical mapping data is the Euclidean distance (Caers 2011; Scheidt et al. 2018; Fig. 3). Of course, for compositional data, all conventional methods can be used, as long as the data are represented in orthonormal log-ratio

coordinates (ilr, clr, balances) (Pawlowsky-Glahn and Buccianti 2011). Here such spatial uncertainty quantifications were introduced in general, and we do not go into mathematical details.

Summary and Conclusions

The uncertainty in the classification models has been approached from two aspects. These are (i) determination of errors in classification and ways in which the errors can be measured and (ii) comparison of different classification models to determine overall stability of the classification and especially samples defined as “anomalous” using the two test datasets where the location of a number of mineral deposits is known. In essence, it is the question of being able to assess the risk that a geochemical “anomaly” is a false indicator of mineralization based on the combination of the nature of the data and the modeling approaches.

In establishing the efficiency of models to accurately classify samples in relation to indications of the actual presence or absence of mineralization, it is again emphasized that the OA model is potentially misleading in quantifying the efficiency of classification models in orientation studies. In the classic contingency tables applied to geochemical sample

Uncertainty Quantification, Fig. 3 Schematic definition of Euclidean distance demonstrating the dissimilarities of different realizations (Sadeghi 2020; modified from Scheidt et al. 2018)

classification and the presence or absence of mineralization, the proportion of “b” samples that display a lack of mineralization signal in an area with no mineralization (or true background) and the “d” samples where there is an anomalous geochemical signal despite no mineralization being present (or the Type II errors) cannot be reliably known. The reason for this is the potential at most scales of geochemical mapping for the existence of unknown or undiscovered mineral deposits and ensuing incorrect allocation of areas or domains on maps as to the “expected background” classification.

The POA approach evaluates the efficiency of the models based only on the known related mineral deposits; hence, it is a partial assessment of efficiency as it relates only to the probability of a geochemical anomaly being present within the dispersion halo of mineralization and not the probability of having no geochemical signal in areas unaffected by mineralization. The POA approach also provides a single scenario in a frequency framework. For cases with different patterns but similar POA, deciding on the most reliable or valid approach to model geochemical data to extract univariate or multivariate patterns or signals related to the effects of mineralization was not valid.

MCSIM modeling, applied to each of the models and their individual characterized population, has partly addressed this problem as a precondition test before either final selection of the models to apply or the decision-making process for selecting the most reliable areas for follow-up exploration. The use of MCSIM on the input data requires initial estimates of (statistical) sampling uncertainty or measurement errors to determine if the potential effects of error propagation on the

final interpolated or simulated models are sufficiently low to allow for modeling to be justified. This is in comparison with a simple visual assessment of the raw data in relation to known mineralization, variations in lithology, structures, and other key supporting data. The MCSIM approach should preferentially be applied to geochemical samples separated into the main domains (typically lithology controlled) but might include landform-regolith associations in terrains different to those in Sweden or Cyprus. The metric to accept the sampling statistical certainty is “return” versus “uncertainty” (Caers 2011; Scheidt et al. 2018). The return must be higher than uncertainty otherwise the sampling (physical or statistical) may need to be improved. This approach has similarity to the question in generating data for purposes of ore reserve estimations of “when to stop drilling” (King et al. 1982).

Unit Regional Production Value

Gunes Ertunc

Department of Mining Engineering, Hacettepe University,
Ankara, Turkey

Definition

The unit regional production value can be described as the accumulated amount of produced resource at a period of time. The proration over a specific region area yields the term unit regional value.

Introduction

The fundamental question underlying the exploration of non-renewable natural resources decision concerns the value of a region when it was developed. The importance of this knowledge emerged when modeling a global strategy for the exploration of nonrenewable natural resources and the feasibility of assessing that particular region. Generally, the value of a region is based on the mineral occurrence which is expressed in terms of prices per area or volume.

The investment decision is based on the potential of the nonrenewable resource in the region. This decision relies on the exploration of this resource, and most of the time, it is risky. One basis, and perhaps the rudimentary way, for estimating the value of resource is the historical production records of similar regions.

In order to compare regions by means of resources and/or reserves, the value of the attribute should be standardized. These standardized values found for the various regions can be used as a comparative tool and can be used as a guide to what to expect in large regions when systematic development is undertaken. Also, this allows to estimate the potential value of a region before the exploration and development phase.

The value of the resources of an area is a variable that varies from one another. Furthermore, their values are independent and do not display conventional random variation. Hence, these values of the mineral resources of a region can be regarded as a good example of a regionalized variable

(actual functions taking a definite value each point of space). Standardizing mineral resource estimations by dividing by its area leads to a regionalized variable called the unit regional value.

Griffiths (1978) suggests mineral resource assessment may be estimated by studying the variation in unit regional value in dollars and/or tons using past production records as a basis. For similar areas or orebodies, this regionalized variable can be used as the basis for resource assessment.

Cybernetic model of mineral resource assessment (Fig. 1) is reproduced from Griffiths (1978). The input of the system is divided into two major characteristics. They are acquired and inherited, respectively. The acquired characteristics are mainly related to financial aspects, such as capital investments, and they can be generalized as socioeconomic factors. On the other hand, inherited characteristics are related to the geological events that control the mineral resources. These inputs pass through the black box processes of exploration to locate the resource, and subsequent exploitation, development, and marketing, and so become transformed into output. The outputs of this system are expressed in dollars, and tonnes are converted to the unit regional value.

In this model, market demand is the main driving force and feedbacks coming from this demand loops the whole system and has a direct influence on capital investments and processes for technologies. Additionally, new discoveries of a new resource also update the geological knowledge, as an input.

To apply the unit regional production value approach to estimate the resources of an area of interest requires a background of information from areas with substantial production over an extended period of time. All regions are presumed that they are equal in value, and then this hypothesis is tested against the production figures. If the hypothesis is accepted, then the expected value of a large region can be used as a guide to the potential value of its smaller subregions.

For example, in the period of 1880–1964, the USA has produced nonrenewable resources to the value of \$399 B, and roughly it is worth 132,309 \$/mi². Of this total, fuels account for 65%, nonmetallics are 19%, and metals represent 16%. It can be concluded that the fuel resources of coal and petroleum products are thus 3 to 4 times more valuable than either of the other kinds of resources (Griffiths 1969).

The estimated averages obtained for a period of time can be used to reveal the production tendencies as well. For example, the difference between the two estimates of average value for the USA (1880–1964 and 1911–1964) is \$5524 per square mile which indicates that the bulk of the value has been produced after 1911.

Each state or subregions productions' and the value of that productions can be compared by means of average value. This average value is equivalent to expected value. The situation is not related entirely to size of deposit, position, or geology. In the example above, while the fuel-rich states achieve, states

Unit Regional Production Value, Fig. 1 Simple cybernetic model of mineral resource subsystem. (Modified from Griffiths 1978)

Unit Regional Production

Value, Fig. 2 Log dollar value per square mile for Kansas, 1960. (Reproduced and modified after Griffiths 1969)

with no outstanding fuel resources also exceed their expected values. Their level of achievement depends essentially on their intensity of development.

Griffiths (1969) analyzed the State of Kansas in terms of value per square mile per county. Kansas has produced mineral industry resources to the value of \$16.2B (in 1911 to 1964) against an expected value of \$6.5B. In this study, mineral industry productions were allocated over counties orthogonal state-wide grid. Then the interpolated contour map is made available. In Fig. 2, the thematic representation of dollars per square mile in log scale is represented. From Fig. 2, the contribution of the petroleum resources of the Central Kansas Uplift can be seen clearly.

Clark et al. (1987) utilizes urv technique in order to estimate the mineral resources of the People's Republic of China.

These estimates are based on geologic comparisons with the 50 US states, and revealed that People's Republic of China is well endowed in major metallic and hydrocarbon resources.

Raju and Misra (1994) were evaluated for different coal-bearing states of India by taking West Bengal as standard.

Summary

The exploration and development of nonrenewable natural resources may be profitable, but the decision to explore is based both on its potential value and the risk involved in realizing this potential. Variation in the unit regional production value can be utilized as a standardized tool for the basis for resource assessment.

Unit Regional Value

Frits Agterberg
Central Canada Division, Geomathematics Section,
Geological Survey of Canada, Ottawa, ON, Canada

Definition

The unit regional value measures the value of all resources of a specific region produced in the past. This total value is prorated over the area of the region considered. The method was invented by J.C. Griffiths at the Pennsylvania State University in 1967 and applied to many regions, especially during the first 20 years after its introduction. The method advocates a systematic approach to the collection of past mineral production data which are integrated using their monetary value. Not only are metal mining and hydrocarbon production data integrated with one another, industrial materials are incorporated as well. Usually, the estimates were conditioned on generalized geological composition of the region.

Introduction

The concept of unit regional value was originally introduced by Griffiths (1967a) in an abstract providing the basic idea and its application to the state of Kansas. This abstract was followed by Griffiths (1968a) explaining the approach in detail. Later it was applied extensively by Griffiths, his PhD and MSc students at the Pennsylvania State University, and by other scientists working on the appraisal of mineral resources. Later detailed descriptions of the method with applications include Griffiths (1978) and Gill and Griffiths (1984).

Basically, the method measures the resources of some specific region in terms of the value of resource produced: this measure is cumulated over the period of production and prorated over the area of the region. For example (*cf.* Griffiths 1978, p. 441), using 1 km² as unit of area, the average unit regional value (*u.r.v.*) of all resources produced over the period 1905 to 1972 for the 48 conterminous states of the USA was \$54,954 (measured in 1967 U.S. dollars). Alaska, on the other hand, possessed a *u.r.v.* of \$2,738 using the same measure. Because the *u.r.v.* of Alaska is about 20 times less than the *u.r.v.* of the conterminous states of the USA, excellent potential for future development on the mineral resources in Alaska is indicated.

A spin-off from the concept of unit regional value was the idea of grid-drilling (Drew 1967). In general, the location of deep drill-holes is based on geological considerations indicating that the probability that a valuable mineral deposit might be located underneath is relatively high at a particular place, for example, as indicated by a geophysical image or its possible occurrence above a geochemical anomaly. However, if mineral resources of different kinds are evenly distributed, a systematic search by grid-drilling might result in unexpected discoveries of hidden resources of many different kinds. Griffiths (1967b) proposed that the USA be systematically explored for nonrenewable mineral resources on a 20-mile square grid. The economic success of this grid-drilling would be based upon this multicommodity approach in which all targets that are economically exploitable are considered desirable and searched for at the same time.

The *u.r.v.* approach and grid-drilling are both based on the assumption that mineral resources of different kinds are evenly distributed across the crust of the Earth when measured systematically and when sufficiently large samples are taken. Systematic inventory is seen as the first step toward discovery of new resources regardless of the nature of the targets that could be of many different kinds.

Incorporation of Geological Information

Originally, the *u.r.v.* estimates were unconditional. However, almost immediately, the method was refined by incorporating quantitative estimates of the geological composition of the regions considered (Griffiths 1968b). Later, a computer system called COMOD was developed (Labovitz et al. 1977). It incorporated quantitative estimates of geological information for any region. Geological maps for the study regions were point-counted yielding proportions by area of each of the lithological units represented on the maps. For purposes of comparing different regions with one another, it is necessary to standardize the rock units distinguished on the maps. The proportions of different rock types were expressed in terms of

65 standardized time-petrographic units (see Griffiths 1978, for details).

Accumulated data for all 50 states of the USA yielded a newly defined diversity index based on 51 rock types. In comparison with other states, Alaska is rich in “detrital high-rank graywacke.” From among the other conterminous states, this made it comparable with the state Nevada according to the COMOD system. Outside the USA, it was found that New Zealand also possesses characteristics which are close to those of Alaska. Since Nevada and New Zealand both possess much higher mineral resource diversity, it is likely that the extra resources produced in these other two regions also should be present in Alaska (Griffiths 1978).

The basic ideas underlying the *u.r.v.* and its generalization incorporating standardized time-petrographic units remain closely associated with John Cedric Griffiths who made other important contributions to mathematical geoscience as well. As discussed in more detail by Donald Singer in Chapter (. . .), Griffiths was one of the founders of the International Association for Mathematical Geosciences which, in 1996, established the Griffiths Award for excellence in the teaching of mathematical geoscience. Griffiths died in 1992 but his geoscientific contributions retain their significance. With respect to *u.r.v.*, incorporation of geological information was later expanded in Griffiths et al. (1997) where, in total, 413 geologic maps at 292 different scales were transformed into a set of 65 three-digit numbers called the time-petrographic index for potential use in other regional *u.r.v.*'s. The approach probably would need significant updating for new applications.

Original Regional Applications

The original *u.r.v.* concept was generalized in different ways. For example, the *u.r.v.*'s of the 48 conterminous states of the USA, when analyzed separately, satisfy a lognormal distribution. Consequently, logarithmically transformed *u.r.v.*'s could be subjected to many standard statistical tests that are based on the normal (Gaussian) distribution. Also, logarithmically transformed *u.r.v.*'s in some applications were subjected to methods of time series analysis (Griffiths 1978). Other generalizations were based on the geology of the regions that were investigated (see previous section). The COMOD software package (Labovitz et al. 1977) standardized mineral resources in terms of 74 commodities and automatically converted the value of resources to deflated 1967 US dollars in all applications.

Gill and Griffiths (1984) listed the regions for which the *u.r.v.* methodology was applied. These include Canada by province (Labovitz 1978), Mexico by state (Chavez-Martinez 1978), South Africa by state (Menzie 1977), Australia by state (Engender 1978), New Zealand (Watson 1977), United Kingdom and Ireland (Walsh 1979), Venezuela by state (Arteaga

1978), and Israel (Gill and Griffiths 1984). In total, areal value estimation studies were carried out for 11 different countries, encompassing a total of 111 politically administratively defined regions such as states or provinces. An important overall conclusion from these many applications was that it could be assumed that all regions above a size of about 5,000 square kms are equally valuable with respect to total endowment in natural resources regardless of their inherent geological characteristics (Griffiths and Singer 1971). Later, the *u.r.v.* methodology was also applied to India by state (Raju and Misra 1991).

A characteristic feature of the *u.r.v.* approach is that it simultaneously considers all commodities produced from the Earth's crust, not only metals and hydrocarbons but also construction materials. In many regions, most of the past production relates to metals, nonmetals, and hydrocarbons. However, in more densely populated regions, most accumulated value can be associated with construction materials. For example, in Israel, the latter accounted for 53.6% of total cumulative output (Gill and Griffiths 1984) followed by non-metals (34.7%), metals (8.0%), and fuels (5.7%).

Summary and Conclusions

The unit regional value (*u.r.v.*) measures the resources of any region in terms of the value of resource produced in the past prorated over the area of the region. In its first example of application (*cf.* Griffiths 1978, p. 441), using 1 km² as unit of area, the average unit regional value (*u.r.v.*) of all resources produced over the period 1905 to 1972 for the 48 conterminous states of the USA was estimated to be \$54,954 (measured in 1967 US dollars). Application to Alaska, on the other hand, resulted in a *u.r.v.* of \$2,738. Because the *u.r.v.* of Alaska is about 20 times less than the *u.r.v.* of the conterminous states of the USA, excellent potential for future development on the mineral resources in Alaska was indicated. In subsequent applications of this approach, the geology of the study regions was incorporated to condition the *u.r.v.* and the computer system COMOD was used. The approach probably would need significant updating for new applications.

Synonyms

Real-valued distributions; Real-valued samples

Definitions

The term “univariate” usually refers to two different entities, namely, distributions and sample statistics. In both cases, it designates a function that depends on a single (typically real) variable.

Univariate Distributions

A real univariate random variable is a function $X: \Omega \rightarrow S \subset \mathbb{R}$. The distribution of X is uniquely characterized by its probability distribution function $F_X(t) = \Pr(X \leq t)$, or by its characteristic function $\phi_X(t) = E(e^{itX})$, where $\mathbf{j} = \sqrt{-1}$ and E denotes the expected value. Examples of univariate distributions are the Poisson and Normal laws.

Univariate Statistics

Consider the sample of real-valued observations $\mathbf{x} = (x_1, x_2, \dots, x_n)$. Sample univariate statistics are transformations of $\mathbf{x}$ that aim at describing interesting quantities.

Overviews

Univariate Distributions

Real random variables can be continuous, discrete, or singular. In practice, only the two first types (and their mixture) are of interest. The distribution of a real continuous random variable is also characterized by its probability density function $f_X(t) = dF_X(t)/dt$; this function is only positive on the support S . The probability function characterizes the distribution of a real discrete random variable. Without loss of generality, assume that the support is a subset of the integer numbers $\mathbb{Z}$. The probability function is the pair $(i, \Pr(X = i))$, for every $i \in S$.

The distribution of both continuous and discrete random variables is the subject of several other Encyclopedia entries. The reader is referred to the compendia by Johnson et al. (1997) for discrete models, and by Johnson et al. (1994, 1995) for continuous distributions.

Univariate Statistics

Some quantities of interest are:

$$\begin{aligned} \text{sample mean } m_1(\mathbf{x}) &= \bar{x} = \frac{1}{n} \sum_{\ell=1}^n x_\ell, \\ \text{sample moment of order } r \ m_r(\mathbf{x}) &= \frac{1}{n} \sum_{\ell=1}^n x_\ell^r, \\ \text{central sample moment of order } r \ \tilde{m}_r(\mathbf{x}) &= \frac{1}{n} \sum_{\ell=1}^n (x_\ell - \bar{x})^r. \end{aligned} \tag{1}$$

Note that $s^2(\mathbf{x}) = m_2(\mathbf{x})$ is the sample variance, and that $s(\mathbf{x})$ is the sample standard deviation. Equation (1) provides an estimate of the location of the distribution that produced the sample $\mathbf{x}$, and $\tilde{m}_2(\mathbf{x}) = m_2(\mathbf{x}) - m_1^2(\mathbf{x}) = s^2(\mathbf{x})$ is an estimate of its variance. All sample moments are well defined, even if their distributional counterparts are not.

Two important higher-order sample moments are the sample skewness and the sample kurtosis. They provide estimates of the asymmetry and the tailedness of the distribution that produced the sample $\mathbf{x}$:

$$\hat{\gamma}_1(\mathbf{x}) = \frac{\tilde{m}_3(\mathbf{x})}{s^3(\mathbf{x})},$$

$$\hat{\gamma}_2(\mathbf{x}) = \frac{\tilde{m}_4(\mathbf{x})}{s^4(\mathbf{x})},$$

and $\hat{\gamma}_2(\mathbf{x}) - 3$ is called “excess kurtosis,” as a reference to the kurtosis of a Gaussian random variable which is 3.

If we may assume that the sample is a collection of independent identically distributed random variables with positive support, it is often interesting to examine the second-kind or log-moments, which are given by

$$k_1(\mathbf{x}) = \frac{1}{n} \sum_{\ell=1}^n \log x_{\ell}, \text{ and}$$

$$\tilde{k}_m(\mathbf{x}) = \frac{1}{n} \sum_{\ell=1}^n (\log x_{\ell} - k_1(\mathbf{x}))^r.$$

Univariate sample statistics can also depend on order statistics. Let $\mathbf{x} = (x_{1:n}, x_{2:n}, \dots, x_{n:n})$ denote the sample $\mathbf{x}$ sorted in nondecreasing order, i.e., $x_{1:n} \leq x_{2:n} \leq \dots \leq x_{n:n}$. The minimum and maximum of $\mathbf{x}$ are, respectively, $x_{1:n}$ and $x_{n:n}$. If the sample size is odd, then the median is $q_{1/2}(\mathbf{x}) = x_{(n+1)/2:n}$. More generally, and regardless of the sample size, the sample quantile of order $\alpha \in (1/n, 1 - 1/n)$ is a weighted average of consecutive order statistics. Hyndman and Fan (1996) provide a comprehensive account of how several computational platforms implement sample quantiles. The interquartile range is the difference $\text{IQR}(\mathbf{x}) = q_{3/4}(\mathbf{x}) - q_{1/4}(\mathbf{x})$.

A summary of sample statistics should contain, at least, the sample size, minimum, first quartile, median, mean, third quartile, and maximum values, as shown in Table 1.

Univariate, Table 1 Summary statistics (rounded to two decimal places)

Name	Notation	Value
Sample size	n	50
Minimum	$x_{1:n}$	0.07
First quartile	$q_{1/4}(\mathbf{x})$	1.09
Median	$q_{1/2}(\mathbf{x})$	2.20
Mean	$\bar{\mathbf{x}}$	2.46
Third quartile	$q_{3/4}(\mathbf{x})$	3.32
Maximum	$x_{n:n}$	6.70

The simplest graphical display of a univariate sample is a “rug plot,” which consists of marks corresponding to each observation along an axis. Rug plots are seldom useful alone; they complement the information provided by the two most commonly seen displays of univariate samples: the boxplot (and variations), and the histogram (and its smoothed versions).

The classical “in the style of Tukey” boxplot shows five summary statistics (the median, two hinges, and two whiskers), and all “outlying” points individually. The hinges are the first and third quartile. The right whisker is set at the smallest value that is larger than or equal to $q_{3/4}(\mathbf{x}) + \frac{1}{2}\text{IQR}(\mathbf{x})$. The left whisker is set at the largest value that is smaller than or equal to $q_{1/4}(\mathbf{x}) - \frac{1}{2}\text{IQR}(\mathbf{x})$. It is useful to plot a notch around the median, usually of size $1.58n^{-1/2}\text{IQR}(\mathbf{x})$ that corresponds to approximately a 95% symmetric confidence interval. Outlying points are above the right whisker and below the left whisker.

Figure 1 shows the elements of the boxplot of the sample whose summary statistics were presented in Table 1. The observations are mapped onto the rug, in maroon (Fig. 1). The only outlying observation is shown as a red dot. Notice that the horizontal grid has been omitted, as it carries no useful information in this plot and may be misleading (Fig. 2).

Boxplots are particularly useful at comparing two or more samples. Figure 2 shows the boxplots of three samples. They have approximately the same sample means, but the spread of the data is noticeably different.

While boxplots are built with summaries based on the sorted sample, the histogram and its variations employ all the data. As such, the rug is a histogram. More often than not, histograms show the counts of observations within disjoint intervals (“bins”), instead of marking each observation as in a rug.

Freedman and Diaconis (1981) studied the properties of histograms as estimators of probability density functions. They proposed the rule known after their names, which states that an optimal bin width is twice the interquartile range divided by the sample size’s cubic root.

The plots in Fig. 3 show the histograms of the same data set: with the default number of bins (30 in the current version of R’s ggplot2 library; cf. Wickham 2016) and with the bin width set by the Freedman-Diaconis rule.

Although histograms as in Fig. 3 provide useful information about the sample, it is hard to show more than one sample at the same time using bars. Kernel smoothing is helpful in such cases, as shown in Fig. 4.

Univariate Fig. 1 Elements of a boxplot with rug

Univariate, Fig. 2 Boxplots of three samples with similar sample mean values

For the sake of reproducibility and replicability, it is a good practice to state the number of bins or the bin width whenever showing histograms, and the kind of kernel and the bandwidth when using smoothed histograms.

Summary

Univariate distributions are always characterized by their cumulative distribution function or by their characteristic

Univariate, Fig. 3 Two histograms and the effect of a judicious choice of the bin width (with the Freedman-Diaconis rule)

Univariate, Fig. 4 Three smoothed histograms with Epanechnikov kernels

function. Univariate statistics provide insights about the underlying model that produced the data.

SOC Self-organized criticality

Definition

The term universality originates in the theory of phase transitions and self-organized criticality. Phase transitions represent changes between different states of matter which occur when a control parameter (e.g., temperature) attains a critical threshold. The correlations of relevant system properties near a phase transition do not fall off exponentially, and thus they do not exhibit characteristic length scales. In contrast, the decay of the correlations follows power-law functions characterized by respective critical exponents. The theory of self-organized criticality posits that certain systems (e.g., sandpiles, avalanches, and geological faults in seismogenous

zones) are close to a critical threshold without tuning a control parameter such as temperature. The term “universality” indicates that phase transitions which occur in different systems are described by the same set of critical exponents, if they share certain geometric and symmetry features; systems with the same values of critical exponents belong in the same universality class (Kadanoff 2000). In a broader sense, universality refers to empirical laws that have global validity, e.g., Gutenberg-Richter’s law which relates the frequency and intensity of earthquakes. The exponent of Gutenberg-Richter’s law surprisingly takes values close to one regardless of geographical location, geological factors, and seismic history.

Overview

The term universality appears in the theories of phase transitions and self-organized criticality (Bak 2013; Kadanoff 2000). The main feature of systems close to a phase transition is that their response functions lack characteristic length scales. Instead, the correlations in such systems decay as power laws, i.e., scale-free functions determined by respective power-law exponents. The concept of universality posits that systems which are quite different in their microscopic details can exhibit identical, i.e., *universal*, macroscopic behavior. More specifically, universality refers to the fact that the power-law exponents, which describe the macroscopic response of different critical systems belonging in the same universality class, take identical values.

The emergence of universality is often justified in terms of the renormalization group (RG) theory introduced by Wilson (1971). RG provides a systematic mathematical framework for predicting the behavior of physical systems (or idealized mathematical models) under a sequence of coarse-graining transformations. These progressively increase the length scale of observation (coarse-graining), while the short-scale details are effaced; at the same time, the impact of coarse-graining on the system parameters is calculated, and their values are accordingly adjusted. Under repeated RG steps, the system “flows” toward limiting states which are known as fixed points. The defining feature of the latter is that a system remains invariant under further coarse-graining transformations at a fixed point.

Phase transitions often involve a jump between a less ordered and a more ordered state. As the transition threshold is approached from the side of the less ordered state, the system is attracted toward a nontrivial fixed point which determines the properties of the more ordered state and the values of its characteristic critical exponents. A universality class encompasses all the models that converge to the same fixed point under application of the RG procedure. Hence, in a broader sense, the term universality refers to the fact that

identical macroscopic physical laws apply to systems which may vary in their microscopic details. For example, the laws of thermodynamics do not depend on the details of atomic interactions, the statistical properties of turbulence in the inertial range are independent of the dissipation mechanisms, and the effective permeability of statistically isotropic random media is insensitive to the exact form of the local permeability correlations. In this sense, universality is a main reason for the success of the scientific approach, since it enables a general understanding of natural phenomena based on a few fundamental physical principles.

More specifically, in the context of geosciences, the term universality is used to imply the global validity of an empirical law across different geographical areas and times. For example, the Gutenberg-Richter law of seismicity is considered a universal law since its validity has been confirmed by countless observations and analysis of seismic catalogs worldwide. The exponent of Gutenberg-Richter's law takes a value close to one, although the exact value may not be universal. Note that strictly speaking, the term "universality" implies not only the same behavior (i.e., power-law), but more importantly also common critical (power-law) exponents for different systems that belong in the same universality class.

The concept of universality is also linked with fractal geometry. The fractal approach was developed and popularized by Benoit Mandelbrot (e.g., as described in his book *The Fractal Geometry of Nature*). Fractal patterns consist of *self-similar* structures which lack characteristic length scales. For example, a fractal object of radius r has surface area $S(r) \sim r^\alpha$ where $\alpha \neq 2$ is a noninteger (fractal) exponent. In phase transitions, fractal patterns (e.g., clusters of the ordered phase) emerge in systems which are close to the critical state. Fractal patterns in systems that belong in the same universality class share the same fractal exponents.

All notions of universality discussed above have applications in the geosciences. Given the wide range of applications and space limitations, it is not possible to cite important early papers by Leo Kadanoff and Per Bak. The interested readers can find more information about these works in the books by Kadanoff (2000) and Bak (2013).

Universality in Phase Transitions

Phase transitions are mechanisms that enable changes between different states of matter, e.g., water, vapor, and ice. Thus, phase transitions play a prominent role in the water cycle of the Earth. There are many types of phase transitions. Some are controlled by temperature (i.e., thermodynamic transitions), while others by the geometry of the medium in which the process takes place (i.e., geometrical transitions). An example in the first class is

the superconducting transition: Metals and ceramic oxides start to conduct electricity without any resistance if the temperature is lowered below a certain critical threshold. An example in the second class is *percolation*: A random porous medium is permeable to fluids if its porosity exceeds a critical threshold. Percolation is key to the production of an aromatic cup of filtered coffee as well as to the infiltration of rainwater into the ground.

Phase transitions are classified as first order and second order. In first-order transitions, the change of state is accompanied by the absorption or release of latent heat, which changes discontinuously the thermodynamic free energy of the system. This leads to a discontinuity in the first derivative of the free energy with respect to a thermodynamic variable (hence the term "first-order"). Typical examples include the condensation of vapor into water droplets (which involves latent heat release) and the melting of ice (mediated by latent heat absorption). In second-order phase transitions, on the other hand, the free energy changes continuously. The discontinuity appears in the susceptibility which is the second-order derivative of the free energy. A typical example is the transition between paramagnetism and ferromagnetism in magnetic materials that takes place at the Curie point. The magnetization of the material acts as the order parameter: It is zero in the paramagnetic phase and takes a finite value in the ferromagnetic state. Similarly, order parameters are defined for other second-order phase transitions (Kadanoff 2000).

Second-order phase transitions are characterized by a set of *critical exponents* that determine how relevant properties scale near the transition point. For example, the exponent ν describes the divergence of the fluctuations' correlation length, i.e., $\xi \sim |T - T_c|^{-\nu}$, where T is the temperature, T_c is the critical temperature, and ξ is the correlation length. The exponent η describes the power-law decay of the correlations with distance at the transition point, i.e., $C(r) \sim r^{-d+2-\eta}$. The exponents α , β , γ , and δ describe the dependence of: (i) the specific heat $c \sim |T - T_c|^{-\alpha}$, (ii) the order parameter $\phi \sim |T - T_c|^\beta$, (iii) the susceptibility of the order parameter to an external field h , i.e., $d\phi/dh \sim |T - T_c|^{-\gamma}$, and (iv) the dependence of the external field on the order parameter $h \sim \phi^\delta$. The critical exponents depend on the dimensionality of the system and the symmetry of the order parameter, but they may be independent of other details (e.g., lattice structure).

Percolation, Fractals, and Multifractals

Percolation is a geometric phase transition which takes place as a connected (e.g., permeable) structure grows in a random medium until it spans the entire extent of the medium. For example, this happens on a lattice system as the proportion of connected sites (e.g., the porosity) approaches a critical

threshold. There exist different percolation models which include site, bond, and continuum percolation (Isichenko 1992). Percolation can be used as a mathematical model for disordered media including heterogeneous geological porous media. The geometric properties of percolation can be applied to analyze transport in such media. Hence, percolation is an important model for the study of subsurface flow and contaminant transport, especially in highly heterogeneous and fractured soils.

Similarly to other phase transitions, percolation involves a critical threshold p_c . This corresponds to the occupation probability above which a fully connected network (medium) becomes possible. The onset of percolation is marked by the emergence of an incipient infinite cluster (essentially a “giant component”) that extends across the medium. The order parameter is given by the probability that a site belongs to this giant component. Other variables describe geometrical patterns of the percolation network (e.g., size of connected clusters, average radius of clusters of given size, probability that two sites at a given distance belong to the same cluster, etc.). Near the percolation threshold, the behavior of such variables is characterized by critical exponents. Universality in the context of percolation means that the critical exponents depend on the dimension of space in which the percolation model is embedded, but they are independent of the lattice structure and the percolation type (site and bond percolation are in the same universality class).

The critical behavior of percolation implies a fractal geometry for the network patterns (e.g., connected clusters) near the percolation threshold. The fractality is bestowed by the critical exponents which in general take noninteger values. The concepts of universality and scaling have found applications in the geometry of naturally occurring fractal patterns such as river networks, fault systems, coastlines, and mountain topography (Isichenko 1992; Dodds and Rothman 2000).

An extended notion of universality is also used in the theory of multifractals. These mathematical models find applications in natural phenomena such as clouds, rain, fluid turbulence, and weather (Lovejoy and Schertzer 2013). Multifractals have more complex scaling relations than fractals. The fractal exponents (dimensions) of multifractals depend on location, and thus a spectrum of exponents is necessary to fully describe multifractal behavior.

Self-Organized Criticality and Earthquakes

A notable application of the concept of universality is the investigation of avalanches in sandpile models by Leo Kadanoff and coworkers in a paper published in 1989 (c.f. Kadanoff 2000). They found different universality classes based on the microscopic rules used for the generation of

avalanches. Their work paved the way for the development of the theory of self-organized criticality (SOC), which describes systems that are always close to a critical threshold without tuning of an external parameter (e.g., temperature).

Self-organized criticality has been proposed as a theoretical framework that among other things can explain the laws of seismicity. In particular, the concept of self-organized criticality provides a possible explanation for the Gutenberg-Richter law which connects the frequency and magnitude of earthquake events (Bak 2013). The fact that earthquakes all over the globe follow the Gutenberg-Richter law is seen as a signature of universality. An influential paper by Olami et al. (1992) argues that the Burridge-Knopoff spring-block model used to simulate earthquakes exhibits *self-organized criticality* but lacks *detailed universality*. This means that the exponent of the Gutenberg-Richter law depends on the elastic parameters of the model (Olami et al. 1992). Recent numerical experiments and lab-generated quakes also show a dependence of the Gutenberg-Richter exponent on the material properties of the medium in which the events take place.

According to a different theoretical approach, the probability distribution of *earthquake recurrence times* follows a universal law, provided that the time between earthquakes is scaled by the local rate of seismic occurrence (Corral 2004). However, this viewpoint is controversial; other researchers argue in favor of an almost-universal law based on the epidemic type aftershock (ETAS) model of seismicity (e.g., Saichev and Sornette 2007).

Summary and Conclusions

The term universality appears in different theories of natural phenomena (phase transitions, self-organized criticality, fractals, and multifractals), and its meaning may differ in each case. The general idea of universality is that certain “universal properties” depend on a few “macroscopic” parameters but are independent of the specific details. A common signature of universality is the presence of power-law dependence, often when a critical threshold is approached. The connection between power-law functions and universality is reviewed in Marković and Gros (2014). Overall, universality is a very fruitful concept which allows studying seemingly disparate systems in the same theoretical framework and has several applications in the geosciences.

Definition

The principal concepts of rough set theory (RST) are reduct, core, and discovering knowledge as a form of rules. In RST, approximations are defined by using a system of definable sets. Upper and lower approximations of Pawlak Rough Set model can be used to generate certain and possible rules based on three disjoint regions, positive negative regions. The rules can explain the decision state to predict new situation. The results obtained show that in Lithology classification problem, this classification approach is quite beneficial because of high accuracy and its explainability.

Background

Since Pawlak proposed rough set theory (Pawlak 1982), a huge number of research results have been provided by means of Rough set theory (RST). RST is an effective tool especially for data mining in various applications. The benefits of RST enable researchers to experiment that. Pawlak explained some advantages in his book on Rough sets (Pawlak 2002; Hossain et al. 2021). RST is an effective tool to work with quantitative and qualitative features similarly without any preliminary information required (Zhang et al. 2016). Particularly RST was found to be useful for imprecise and inconsistent information systems to generate logical relations and feature selection. RST requires to go through some steps to induce rules from the decision table.

Based on a pair of approximations: upper approximation and lower approximation in RST, it is possible to learn from the examples and generate rules which are known as LERS system (Sudha and Kumaravel 2018). RST handles inconsistent information which allows to calculate lower and upper approximation results as two types of rules: certain rules and possible rules (Grzymala-Busse 1992). By calculating the certain and possible rules from the upper and lower approximations, classification problems can be solved.

This entry includes the application of lower approximation and upper approximation in generating certain and possible rules for solving lithology classification problem which is of major importance in oil and gas exploration because lithology represents the reservoir petrophysical characteristics (Hossain et al. 2020a, b).

Methodology

Decision Table and Informatixon System (IS)

RST requires the dataset to be arranged as a decision table where in the columns there are some dependent features and some independent features. Each column consists the values that indicate the property for the observations. Along the row of the table, the examples or the objects are arranged. Such a table is called an information table. An information system, on the other hand, is a pair $I = (U, K)$, where the universe is denoted as U and the feature set is denoted as K (both U and K are nonempty finite). Mathematically, $k : U \rightarrow V_k$ for $k \in K$, where V_k is denoted as the domain of k . A decision table is a form of IS that represents the retrievable knowledge in the system. Formally, decision table, $I = (U, K \cup D)$, where features in K are called condition feature and D is the decision feature. The conditional features, also known as independent features, consist of the conditional values of an object to get into a decision. Decision features may consist of binary categories I or multiple classes.

Upper Approximation,**Fig. 1** Data partitioning based on RST approximations for a set Y**Approximations in RST**

An important concept of RS is the indiscernibility relation that is formed by information that concerns the data of interest. The idea of the indiscernibility relation is to explain that due to the deficiency of knowledge it is not difficult to distinguish several objects in the concerning information system. Another vital concept of RST is approximations. In RST, there is a pair of approximations: *lowerApproximation* concerns with the object samples which definitely belong to the interest subset. On the contrary, *upperApproximation* concerns about the objects that might possibly belong to the interest subset. *Boundary Region* consists of the samples which cannot be identified as any approximation type.

Mathematically, let a set $Y \subseteq U$, C be an equivalence relation and a knowledge base $N = (U, C)$. So, the approximations can be denoted as:

$$C_*(Y) = \{y \in U : C(y) \subseteq Y\} \quad (1)$$

$$C^*(Y) = \{y \in U : C(y) \cap Y \neq \emptyset\} \quad (2)$$

Above, $C_*(Y)$ and $C^*(Y)$ are called the *C-lower-approximation* and the *C-upper-approximation* of Y , respectively.

The *boundary region* is defined as,

$$CN_C(Y) = C^*(Y) - C_*(Y) \quad (3)$$

If the borderline area of Y is empty which means if $CN_C(Y) = \emptyset$, then dataset Y is considered to be exact in

C . In other words, if $C_*(Y) = C^*(Y)$, then Y is a crisp set. Else if $CN_C(Y) \neq \emptyset$, then the data set Y is a rough set in C . Figure 1 demonstrates the definitions.

RS can be explained by a rough membership function as well (as shown below) (Hossain et al. 2021):

$$\mu_y^C(y) = |Y \cap C(y)| / |C(y)| \quad (4)$$

Apparently,

$$\mu_y^C(y) \in [0, 1] \quad (5)$$

where $\mu_y^C(y)$ is a kind of conditional probability that is represented as a degree of certainty to which y belongs to Y (or $1 - \mu_y^C(y)$).

The rough membership function can also be used for expressing the *approximations* and the *boundary region* of a set,

$$C_*(Y) = \{y \in U : \mu_y^C(y) = 1\}, \quad (6)$$

$$C^*(Y) = \{y \in U : \mu_y^C(y) > 0\}, \quad (7)$$

$$CN_C(Y) = \{y \in U : 0 < \mu_y^C(y) < 1\}. \quad (8)$$

Now we can give two definitions for rough sets shown as follows:

Definition 1 Set Y is rough with respect to C if,

$$C_*(Y) \neq C^*(Y) \quad (9)$$

Definition 2 Set Y is rough with respect to C if for some y ,

$$0 < \mu_y^C(y) < 1 \quad (10)$$

Reduction of Features

Feature reduction is a vital aspect of RST. Reducing the redundant information from the system but at the same time to keep the relation of indiscernibility is the key idea of this step. The target is to search for indispensable features and eliminating the dispensable features.

If k is an indiscernible feature in K , deleting it from the information system I will cause I to be inconsistent. In the other hand, if a feature is discernible, it could be eliminated from the dataset, and in this way the dimensionality of the dataset will be reduced.

Let L be a subset of K and k belongs to L . The following exist:

1. If $I(L) = I(L - \{k\})$, then k is *discernible* in L ; or else k is *indiscernible* in L .
2. If features are necessary, then L is *independent*.
3. If $I(L') = I(L)$ and L' is independent, then L' , the subset of L , is an L 's reduction.

Reduction consists of some functions. First, the core of the features is calculated. *Core* is basically the feature set in where the features are present in all the *reducts*. In another words, a Core consists of the features which are indispensable from the information system devoid of breaking the structure of the similarity class. Let us assume L to be a subset of K . Then the set of the necessary features in L is the *core* of L . *Core* and *reduction* are related in the following way:

$$\text{Core}(L) = \cap \text{Reduct}(L) \quad (11)$$

where $\text{Reduct}(L)$ is the list of all the reductions s of L .

Certain and Possible Rules Generation

Once the reduction is done, the *core* finding is done for the examples. *Core* is derived with the condition that the table still needs to be consistent (Hossain et al. 2021; Hossain et al., 2–5, December 2018). Then certain rules are generated from the consistent portion of the information table. In certain rules generation, lower approximation set is taken into account. Which means, the inconsistent objects are ignored to generate only the definite rules.

Once the certain rules are generated, the possible rules can also be generated by considering upper approximation. Which means the inconsistent objects are also taken into account for generating the rules.

Experimental Steps

Data Collection

A collection of 2747 samples and 13 well log features are considered where ten major lithology classeslithology class found in the well namely Mudstone, Claystone, Sandstone, Siltston, Sandy Siltstone, Sandy Mudstone, Silty Sandstone, Muddy Sandstone, Silty Mudstone, and Granulestone are the categories to be classified by the methodology.

Table 1 shows the information of the lithology classeslithology class and the assigned class number.

Discretization

There are 12 well log conditional features such as Gamma Ray, Neutron Porosity, Density Correlation, Photo Electric Effect, Density Porosity, Conductivity, Caliper, Borehole Volume, Compressional Sonic, Hole Diameter, SQp, and SQs.

For applying the methodology, the above mentioned conditional features need to be discretized. In this experiment, each of these conditional features is discretized into 10 equal length intervals.

Upper and Lower Approximations

Based on the RST theory, for the training samples belonging to each particular class, the lower and the upper approximations are found.

The quality and accuracy of approximation can be computed with the RST approximations. The accuracy of approximations lies between $[0,1]$.

The accuracy of approximation is defined as

Upper Approximation, Table 1 Lithology classeslithology class and their corresponding information

Upper Approximation, Fig. 3 Approximation rules. (Note this is based on Rose 2 <http://idss.cs.put.poznan.pl/site/rose.html>)

$$\text{Approximation accuracy} = \frac{\text{No. of objects in lower approximation}}{\text{No. of objects in upper approximation}} \quad (12)$$

The figure below shows the sample sizes for upper and lower approximations for each class.

Certain and Uncertain Rules Generation

1. In Fig. 2, we can see that, other than class no. 8, the approximation accuracy is less than 1.

2. Since, for class no. 8, lower approximation = upper approximation, only certain rules can be generated from this class and no possible rules are needed.
3. For all the classes except class no. 8, both certain and possible rules can be generated.
4. Sample Certain and Possible rules are shown in Fig. 3. Rules no. 47–51 are certain rules. And Rules No. 52–54 are possible rules.

Classification Using the RST Rules

The rules that are found in section “[Certain and Uncertain Rules Generation](#)” are implemented on the test dataset for classifying the objects and computing the accuracy.

1. First, the certain rules are applied on the testing samples.
2. Then the possible rules are applied to the samples that could not be classified by the certain rules.
3. The classification accuracy is 84.83% and the misclassification rate is 15.17%.
4. The computation of minimizing the decision rules is a combinatorial computation. It is time-consuming. Kim et al. (2013) and Kim et al. (2011) enable us to solve the fast solution of RST by using DNA computation.

Summary

In this entry, a classification method based on upper and lower approximations for generating possible and certain rules is shown and a real time application is also provided to solve the lithology identification problem. The conclusions are as follows:

1. By using the RST approximations, certain and possible rules can be generated and data inconsistency is handled.
2. The generated rules are usable for classifying the decision classes for the future objects.
3. The classification accuracy is 84.83%. Therefore, the model can be adapted as a real-world solution to lithology classification.
4. The rules provide explainability to the model which helps the researchers to extract the reasoning for the classifications of the objects.

Synonyms

Second-order moment; Standard deviation

Definition

The variance of a regionalized variable measures the dispersion around the expected value and it is defined as the expected value of the squared difference between the random variable and its expected value.

Overview

In spatial statistics, the observed value $z(\mathbf{x})$ of a given aspect of interest at the location $\mathbf{x}$ is considered as a particular realization of the corresponding random variable $Z(\mathbf{x})$, and the set of the random variables $\{Z(\mathbf{x}), \mathbf{x} \in V\}$, where $V \subseteq \mathbb{R}^d$, $d \in \mathbb{N}_+$ ($d \leq 3$), is called spatial random field. It is important to point out that in the applications, the sample data could be measured on points or blocks. If the spatial data refer to a block both its location and its volume (in terms of shape and size, which define the support of the sample) have to be considered. Moreover, if the volume of the blocks is very small and equal for all the sample data, it can be neglected and the sample data can be treated as points (Isaaks and Srivastava, 1989).

In the following, the first- and second-order moments of $Z(\cdot)$ are provided and the central role of the variance is highlighted in the geostatistical context.

Given a random variable $Z(\mathbf{x})$ at the point $\mathbf{x}$, its *first-order moment* depends on the spatial location $\mathbf{x}$ and it is defined as follows:

$$E[Z(\mathbf{x})] = m(\mathbf{x}), \quad \mathbf{x} \in V,$$

while the *second-order moments* are given below:

- *Variance*, also known as a priori *variance*, which measures the dispersion of $Z(\mathbf{x})$ around its expected value $m(\mathbf{x})$

$$\text{Var}[Z(\mathbf{x})] = E[Z(\mathbf{x}) - m(\mathbf{x})]^2, \quad \mathbf{x} \in V. \quad (1)$$

The variance can also be written as $\text{Var}[Z(\mathbf{x})] = E[Z^2(\mathbf{x})] - [m(\mathbf{x})]^2$; thus, when the expectation of $Z(\mathbf{x})$ is zero, the variance corresponds to $E[Z^2(\mathbf{x})]$.

- *Covariance*, which is defined as follows:

$$C[Z(\mathbf{x}), Z(\mathbf{x}')] = E\{[Z(\mathbf{x}) - m(\mathbf{x})][Z(\mathbf{x}') - m(\mathbf{x}')]\}, \quad \mathbf{x}, \mathbf{x}' \in V; \quad (2)$$

it exists if the variance of the two random variables $Z(\mathbf{x})$ and $Z(\mathbf{x}')$ is finite.

- *Variogram*, which measures the variance of the increments between $Z(\mathbf{x})$ and $Z(\mathbf{x}')$

$$2\gamma[Z(\mathbf{x}), Z(\mathbf{x}')] = \text{Var}[Z(\mathbf{x}) - Z(\mathbf{x}')] \quad \mathbf{x}, \mathbf{x}' \in V. \quad (3)$$

Note that the function γ is called *semivariogram*.

Looking at the second-order moments of a regionalized variable, the variance measures the spread of the phenomenon around the mean, and is a measure of the dissimilarity between $Z(\mathbf{x})$ and $Z(\mathbf{x}')$.

The covariance (2) and the variogram (3) depend on the support points $\mathbf{x}$ and $\mathbf{x}'$, hence many realizations of the random variables at the points $\mathbf{x}$ and $\mathbf{x}'$ are necessary to make statistical inference on these moments. However, the spatial data are non-repetitive, since only one observation is available in every single location. To overcome this inferential problem, the stationarity hypotheses have to be introduced, which assume that the observations at the spatial points characterized by the same separation vector $\mathbf{h}$ (in length and direction) are considered as replicates of the pair $Z(\mathbf{x})$ and $Z(\mathbf{x}')$. In particular, a random field is second-order stationary if

- The expected value does not depend on the spatial point $\mathbf{x}$: $E[Z(\mathbf{x})] = m, \mathbf{x} \in V$.
- The covariance only relies on the separation vector $\mathbf{h}$ and not on the spatial locations $\mathbf{x}$ and $\mathbf{x}'$:

$$C(\mathbf{h}) = E\{[Z(\mathbf{x}) - m][Z(\mathbf{x} + \mathbf{h}) - m]\}, \quad \mathbf{x}, \mathbf{x} + \mathbf{h} \in V;$$

where $\mathbf{h} = (|\mathbf{h}|, \alpha)$ is the separation vector, whose elements are $|\mathbf{h}|$, which is the length of the vector and α , which is the corresponding direction.

The stationarity of the covariance implies the stationarity of the variance and of the variogram (Journel and Huijbregts 1978), as specified hereinafter.

- For $\mathbf{h} = \mathbf{0}$ the covariance is equal to the variance

$$\begin{aligned} C(\mathbf{0}) &= E\{[Z(\mathbf{x}) - m][Z(\mathbf{x}) - m]\} = E[Z(\mathbf{x}) - m]^2 \\ &= \text{Var}[Z(\mathbf{x})], \quad \mathbf{x} \in V; \end{aligned} \quad (4)$$

hence, all the random variables over the same spatial domain have the same expectation and the same finite variance.

- For any couple of random variables $Z(\mathbf{x})$ and $Z(\mathbf{x} + \mathbf{h})$ the variogram is equal to

$$\begin{aligned} 2\gamma(\mathbf{h}) &= \text{Var}[Z(\mathbf{x} + \mathbf{h}) - Z(\mathbf{x})] \\ &= E[Z(\mathbf{x} + \mathbf{h}) - Z(\mathbf{x})]^2, \quad \mathbf{x}, \mathbf{x} + \mathbf{h} \in V. \end{aligned} \quad (5)$$

From (5) it can be proved that if two random variables are separated by a vector $\mathbf{h}$, then the semivariogram γ is strictly related to the variance and the covariance through the following relation

$$\gamma(\mathbf{h}) = C(\mathbf{0}) - C(\mathbf{h}), \quad (6)$$

where $C(\mathbf{0}) = \text{Var}[Z(\mathbf{x})]$. In addition, under the second-order stationarity hypothesis, it is assumed the existence of the covariance and, consequently, of a finite a priori

variance. Moreover, the covariance is a bounded function, namely, $|C(\mathbf{h})| \leq C(\mathbf{0})$, then, according to (6), also the variogram is bounded by $C(\mathbf{0})$. However, for some phenomena the variance and the covariance do not exist in finite form; in this case it is convenient to resort to the intrinsic hypotheses, which are based on the second-order stationarity of the increments between $Z(\mathbf{x} + \mathbf{h})$ and $Z(\mathbf{x})$. In particular, given a separation vector $\mathbf{h}$:

- The expected value of the increments is supposed to be equal to zero:

$$E[Z(\mathbf{x} + \mathbf{h}) - Z(\mathbf{x})] = 0, \quad \mathbf{x}, \mathbf{x} + \mathbf{h} \in V;$$

- The variance of the increments $[Z(\mathbf{x} + \mathbf{h}) - Z(\mathbf{x})]$ is finite and does not depend on $\mathbf{x}$: $2\gamma(\mathbf{h}) = \text{Var}[Z(\mathbf{x} + \mathbf{h}) - Z(\mathbf{x})] = E[Z(\mathbf{x} + \mathbf{h}) - Z(\mathbf{x})]^2, \mathbf{x}, \mathbf{x} + \mathbf{h} \in V$.

Variance for an Indicator Random Field

In some applications it is interesting to evaluate the probability whether or not a random variable at unsampled locations exceeds a fixed threshold. For this aim it is relevant introducing the indicator random field and the corresponding variance.

Given a second-order stationary random field $\{Z(\mathbf{x}), \mathbf{x} \in V\}$ where $V \subseteq \mathbb{R}^d$ and a fixed threshold $z \in \mathbb{R}$, the indicator random field $\{I(\mathbf{x}; z), \mathbf{x} \in V\}$ is such that

$$I(\mathbf{x}; z) = \begin{cases} 1 & \text{if } Z(\mathbf{x}) \leq z, \\ 0 & \text{otherwise.} \end{cases}$$

The variance of an indicator random field is finite and equal to

$$\text{Var}[I(\mathbf{x}; z)] = F(z) - F^2(z), \quad (7)$$

where $F(\cdot)$ denotes the marginal distribution of $Z(\mathbf{x})$.

The remarkable characteristic of the variance of an indicator random field is that its maximum value is 0.25 for $z = z_M$, where z_M is the median of the distribution of $F(z)$, hence $F(z_M) = 0.5$.

Properties of the Variance

Given a random variable $Z(\mathbf{x})$ at the spatial location $\mathbf{x}$, the following properties of the variance are provided:

1. $\text{Var}[Z(\mathbf{x})] \geq 0$,
2. $\forall a \in \mathbb{R}, \quad \text{Var}(a) = 0$,
3. $\forall a \in \mathbb{R}, \quad \text{Var}[Z(\mathbf{x}) + a] = \text{Var}[Z(\mathbf{x})]$,
4. $\forall a \in \mathbb{R}, \quad \text{Var}[aZ(\mathbf{x})] = a^2 \text{Var}[Z(\mathbf{x})]$.

Moreover, given the regionalized variables $Z(\mathbf{x}_i)$, $i = 1, \dots, N$, the variance of a sum of random variables results as follows:

$$\text{Var} \left[\sum_{i=1}^N Z(\mathbf{x}_i) \right] = \sum_{i=1}^N \text{Var}[Z(\mathbf{x}_i)] + 2 \sum_{i=1}^{N-1} \sum_{j=i+1}^N C[Z(\mathbf{x}_i), Z(\mathbf{x}_j)]$$

where $C(\cdot)$ is the covariance function. Starting from the first property of the variance, the admissibility condition for a function to be a covariogram (i.e. the condition of positive definiteness) can be derived.

The variance of the vector $\mathbf{Z} = [Z(\mathbf{x}_1), Z(\mathbf{x}_2), \dots, Z(\mathbf{x}_N)]$ can also be written in matrix form, which is known in the literature as variance-covariance matrix, usually indicated with the Greek letter Σ . This matrix, of order $(N \times N)$, contains the variances of the regionalized variables $Z(\mathbf{x}_i)$, $i = 1, \dots, N$ on the diagonal, while the off-diagonal entries are the covariances between the variables, i.e.,

$$\Sigma = \begin{bmatrix} \text{Var}[Z(\mathbf{x}_1)] & C[Z(\mathbf{x}_1), Z(\mathbf{x}_2)] & \cdots & C[Z(\mathbf{x}_1), Z(\mathbf{x}_N)] \\ C[Z(\mathbf{x}_2), Z(\mathbf{x}_1)] & \text{Var}[Z(\mathbf{x}_2)] & \cdots & C[Z(\mathbf{x}_2), Z(\mathbf{x}_N)] \\ \vdots & \vdots & \ddots & \vdots \\ C[Z(\mathbf{x}_N), Z(\mathbf{x}_1)] & C[Z(\mathbf{x}_N), Z(\mathbf{x}_2)] & \cdots & \text{Var}[Z(\mathbf{x}_N)] \end{bmatrix}.$$

Note that the Σ matrix is symmetric and positive semi-definite (Schott 2018).

Sample Variance

As previously pointed out, the a priori variance of a second-order stationary random field is finite and corresponds to $C(\mathbf{0})$, on the other hand if Z satisfies the intrinsic hypotheses but not the second-order stationarity ones, then $\text{Var}[Z(\mathbf{x})]$ might not be finite, however, and the variance of the increments between $Z(\mathbf{x} + \mathbf{h})$ and $Z(\mathbf{x})$ is finite.

Given the random variables $Z(\mathbf{x}_i)$, $i = 1, \dots, N$, of a random function Z , the estimator of the variance is the *sample variance*, whose analytic expression is given below:

$$S^2 = \frac{1}{N} \sum_{i=1}^N [Z(\mathbf{x}_i) - \bar{Z}]^2, \quad \mathbf{x}_i \in V, \quad (8)$$

where $\bar{Z} = \frac{1}{N} \sum_{i=1}^N Z(\mathbf{x}_i)$ is the sample mean.

Alternatively, the sample variance can also be expressed in terms of the sum of the squared differences between all the random variables $Z(\mathbf{x}_i)$

$$S^2 = \frac{1}{2N^2} \sum_{i=1}^N \sum_{j=1}^N [Z(\mathbf{x}_i) - Z(\mathbf{x}_j)]^2, \quad \mathbf{x}_i, \mathbf{x}_j \in V. \quad (9)$$

It is important to point out that the sample variance is a random variable; hence it is characterized by first- and second-order moments. In particular, the expected value of the sample variance, denoted by σ^2 , is obtained as follows (Chilès and Delfiner 2012):

$$E(S^2) = \sigma^2 = \frac{1}{N^2} \sum_{i=1}^N \sum_{j=1}^N \gamma(\mathbf{x}_i - \mathbf{x}_j)^2. \quad (10)$$

Moreover, for second-order stationary random functions, the expected value of the sample variance (10) is also equivalent to

$$E(S^2) = \sigma^2 = C(\mathbf{0}) - \frac{1}{N^2} \sum_{i=1}^N \sum_{j=1}^N C(\mathbf{x}_i - \mathbf{x}_j). \quad (11)$$

Hence, starting from the equivalence in (11) the following relation can be derived: $\sigma^2 < C(\mathbf{0})$. In addition, if the sample locations are so far apart, which means that the regionalized variables are uncorrelated, the expectation of the sample variance is equal to

$$E(S^2) = \sigma^2 = \left(1 - \frac{1}{N}\right) C(\mathbf{0}), \quad (12)$$

where the difference between σ^2 and $C(\mathbf{0})$ vanishes as the sample size increases.

Estimation Variance

It is well known that in Geostatistics the estimation of a regionalized variable at unsampled spatial locations, obtained through different techniques, is a relevant aspect. The estimation error occurs in every estimation technique due to the fact that the quantity to be estimated generally differs from the estimate.

Given a random function Z over a spatial domain V , Z takes its values $Z(\mathbf{x})$ on small regular-shaped areas v centered on $\mathbf{x}$, and if the support v is a point its area is negligible with respect to V . Assuming that the true value $z(\mathbf{x}_i)$ is estimated through $\hat{z}(\mathbf{x}_i)$, the estimation error is equal to $r(\mathbf{x}_i) = \hat{z}(\mathbf{x}_i) - z(\mathbf{x}_i)$. Then, the error $r(\mathbf{x}_i)$ is a particular realization of the random variable $R(\mathbf{x}_i) = \hat{Z}(\mathbf{x}_i) - Z(\mathbf{x}_i)$, $i = 1, \dots, N$. Note that if the random field Z is stationary, also $R(\mathbf{x})$ is stationary; moreover

since $R(\mathbf{x})$ is a random variable it is relevant to evaluate its first- and second-order moments (Journel and Huijbregts 1978) that are:

- the expected value $E[R(\mathbf{x})] = m_E, \forall \mathbf{x}$;
- the variance (or *estimation variance*) $Var[R(\mathbf{x})] = E[R(\mathbf{x})]^2 - m_E^2 = \sigma_E^2, \forall \mathbf{x}$

The estimation of the above-mentioned moments is required since a good estimation technique ensures a mean error equal to zero and the smallest estimation variance. In particular, the estimator $\hat{Z}$ must be a function of $Z(\mathbf{x}_i)$

$$\hat{Z}(\mathbf{x}) = f\{Z(\mathbf{x}_1), Z(\mathbf{x}_2), \dots, Z(\mathbf{x}_N)\}$$

and it is such that:

- The unbiasedness condition is satisfied, i.e., $E[R(\mathbf{x})] = E[\hat{Z}(\mathbf{x}) - Z(\mathbf{x})] = 0$.
- It is possible to compute easily the estimation variance, i.e., $Var[R(\mathbf{x})] = \sigma_E^2 = Var[\hat{Z}(\mathbf{x}) - Z(\mathbf{x})]$

For any function $f(\cdot)$, the calculation of the expected value and of the variance of the random variable $R(\cdot)$ requires that the distribution of $Z(\mathbf{x}_i)$, $i = 1, \dots, N$, is known. Nevertheless, since it is generally not possible to infer this distribution from a unique realization of $Z(\mathbf{x})$, usually the class of the linear $\hat{Z}$ is chosen in estimators (Journel and Huijbregts 1978):

$$\hat{Z} = \sum_{i=1}^N \lambda_i Z(\mathbf{x}_i). \quad (13)$$

Hence, given a stationary random field Z , if $\hat{Z}$ is chosen in the class of the linear estimators the unbiasedness condition is ensured if $\sum_{i=1}^N \lambda_i = 1$ and the estimation variance (Matheron 1963, 1965) corresponds to

$$\sigma_E^2 = 2\bar{\gamma}(v, V) - \bar{\gamma}(V, V) - \bar{\gamma}(v, v), \quad (14)$$

or, more specifically can be calculated as follows:

$$\sigma_E^2 = 2 \sum_{i=1}^N \lambda_i \bar{\gamma}(\mathbf{x}_i, V) - \bar{\gamma}(V, V) - \sum_{i=1}^N \sum_{j=1}^N \lambda_i \lambda_j \gamma(\mathbf{x}_i, \mathbf{x}_j), \quad (15)$$

where

- $\bar{\gamma}(\mathbf{x}_i, V) = \frac{1}{|V|} \int_V \gamma(\mathbf{x}_i, \mathbf{x}) d\mathbf{x}$, is the average semivariogram between the sampling points $\mathbf{x}_i$ and all the other points in the domain V ;
- $\bar{\gamma}(V, V) = \frac{1}{|V|^2} \int_V \int_V \gamma(\mathbf{x}, \mathbf{x}') d\mathbf{x} d\mathbf{x}'$, is the average semi-variogram over V

From (14) or (15) it is possible to conclude that σ_E^2 does not depend on the shape and size of the area under study, the relative locations of the sample data within V as well as the spatial correlation structure γ .

Hence, σ_E^2 is strictly related to the model chosen for modeling γ , keeping constant the area V and the location of the sample data.

Note that, by minimizing the estimation variance σ_E^2 , the Ordinary Kriging (OK) estimator is obtained (Stein, 1999). Hence, in the class of the linear weighted average estimators, the kriging provides the best linear unbiased estimator (B.L. U.E.), since the optimal weights λ_N minimize the estimation variance σ_E^2 , under the constraint $\sum_{i=1}^N \lambda_i = 1$. It is well known that different forms of kriging are available in the literature and each type is characterized by a specific estimation variance. In the contributions of Journel and Huijbregts (1978) and Journel (1977) the hierarchy among the estimation variances is detailed, that is $\sigma_{E_{DK}}^2 \leq \sigma_{E_{SK}}^2 \leq \sigma_{E_{OK}}^2 \leq \sigma_{E_{UK}}^2$, where $\sigma_{E_{DK}}^2$ is the estimation variance associated to the disjunctive kriging, $\sigma_{E_{SK}}^2$ is the one associated with the simple kriging, while $\sigma_{E_{OK}}^2$ and $\sigma_{E_{UK}}^2$ refer to the estimation variance in case of ordinary and universal kriging, respectively.

Dispersion Variance

The term *dispersion variance*, as clarified in Journel and Huijbregts (1978), is used in Geostatistics to denote:

- The dispersion around the mean value of a set of data collected within a domain V . This dispersion increases as the dimension of the spatial domain increases.
- The dispersion within a fixed domain V with respect to the support v . This dispersion decreases as the support v on which each datum is defined increases.

The dispersion variance of the support v within the spatial domain V also depends on the variogram:

$$D^2(v|V) = \bar{\gamma}(V, V) - \bar{\gamma}(v, v). \quad (16)$$

From the relationship in (16) it is evident that as the support v increases, then $\bar{\gamma}(v, v)$ increases, hence the dispersion variance $D^2(v|V)$ decreases, keeping other factors constant. For the extreme case in which the spatial unit is a point ($v = 0$), the dispersion variance in terms of variogram, corresponds to

$$D^2(0|V) = \bar{\gamma}(V, V). \quad (17)$$

It is important to note that the dispersion variances in (16) and (17) are linked by the additive relationship that is:

$$D^2(0|V) = D^2(0|v) + D^2(v|V).$$

This property explains the drop of the variance when the support changes from a quasi point sample support to a larger support of interest:

$$D^2(0|V) - D^2(v|V) = D^2(0|v) = \bar{\gamma}(v, v).$$

Summary

In spatial statistics the second-order moments of a random variable $Z(\mathbf{x})$ at the location $\mathbf{x}$ are always evaluated. In particular, the variance measures the dispersion of the random variable around its expected value.

In this chapter, the first- and second-order moments of $Z(\cdot)$ are provided and the central role of the variance is highlighted in the geostatistical context.

Definition

A variogram is a tool to describe the data spatial continuity. When a number of data samples are available, the analyst can use a variability measure between each pair of the samples at different distances to calculate the experimental variogram function considering the best type of the variogram fitted (Deutsch and Journel 1998).

Introduction

Geostatistics is the combination of different disciplines of geology and statistics. Its main focus is on spatial and spatiotemporal types of dataset in various fields of geosciences and engineering. One of the significant and basic concepts in geostatistics is variogram, its different types, and the variography. A variogram is a function to describe the data spatial continuity using the variability between sample points located at different distances from each other and affecting each other considering the distances (lags). In actual, it helps with finding the highest distance between the samples in which the samples are spatially in relation and affecting each other. In other words, closer samples have lower variabilities, i.e., higher spatial effects, yet the distant samples provide higher variabilities, i.e., lower spatial effects. The final interpolation would be implemented on those samples which are situated in that effective range.

Samples and Datasets

In the geosciences, we may have various types of samples in 2D (on the ground) or 3D (under the ground and subsurface), such as litho, soil, till, rock chip, and stream sediment samples. Based on the study for which the samples are collected, one looks for something specific as the target value, i.e., data. For instance, in geochemical studies, that value could be the concentration of the target elements in various samples.

Interpolation

In general, mostly in geological studies, due to lack of access to some parts of the study areas like mountainous areas, or even lack of budget, which is always critical, the number of the samples collected is limited. Based on the experts' opinion and the exploration level and scale (e.g., reconnaissance, regional, local, and detailed exploration), the sampling network could be regular or irregular and dense or scarce, and even the distance between samples could be short in meters or higher than kilometers. To generate a final continuous map based on the sample values to provide a better imagination about the mineral deposits, their concentrations, and trend, we need to estimate the values in the unsampled areas as well, however based on those in sampled areas. To do so, we need to apply interpolation methods.

A group of multivariate interpolation methods are applicable in geostatistical analysis considering the type of samples and studies. Some of the more conventional methods are bilinear interpolation and nearest-neighbor interpolation, which are mainly based on the distance between samples.

Generally, in geochemical surface map generation procedures and exploration projects, *weighted moving average* (WMA) interpolation techniques have been significantly taken into consideration. Inverse distance weighting (IDW) and kriging are among the most common WMA techniques (Carranza 2009). The IDW interpolation technique considers both distances between samples and the spatial effect of samples on each other considering that distance (assigned as weight). Simply, this method says the closer samples have higher effects (assigned weights) on each other than the distant samples (Fig. 1). This interpolation technique is mostly applicable to 2D modeling/mapping; however, in 3D modeling, it has some limitations, which are out of this entry's scope. To apply this technique, we need to have a knowledge of the point uni-element concentration data. This helps with better adjustments of the "moving average" window (or kernel) size and distance (assigned as weight) parameters (Carranza 2009).

$$Z = \frac{\sum_{i=1}^n \left(\frac{z_i}{d_i^p} \right)}{\sum_{i=1}^n \left(\frac{1}{d_i^p} \right)}$$

Z: target element concentration

z_i : concentration in i th sample

d: distance

n: number of samples

* The optimum value of p is often 2.

Variogram, Fig. 1 The simplified concept of IDW

The main point raised here is we may have a local group of samples together, in addition to several other samples in various distances from them. Can we use all those samples for the interpolation? Does it make the final interpolation biased? Do those samples really have any spatial effect on the main group of samples? If so, how much? If not, considering the samples' values and their variances, what samples could effectively get involved with the estimation and what samples will not have any spatial effect? This means we need to have a distance range in which all samples are in spatial relationship, and they are proper for interpolation, and the rest of the samples beyond that range have no spatial effect and association and will not be used for the interpolation (Fig. 2). To do so, we need a new concept or interpolation method. Kriging interpolation/estimation was developed based on such a search radius (Sagar et al. 2018; see the entry "Kriging"). Kriging, as a Gaussian process regression, is the most important interpolation method in geostatistics that provides the best linear unbiased estimation (BLUE) based on covariances (Deutsch and Journel 1998). It applies Gauss-Markov theorem to demonstrate the estimation/error independence. The main difference between kriging and regression is that kriging is applied to an individual realization of a single random field, but the regression is multiple scenarios of multivariate dataset. To apply kriging interpolation (see the entry "Kriging"), or Gaussian simulation to generate more than a single scenario (i.e., realizations) based on the same data – see the entries "Simulation," "Sequential Gaussian Simulation," and "Uncertainty Quantification" – variogram is required.

Variogram Main Principles

In Fig. 2, imagine the distances between two samples of A and B, and B and C are 50 m and 100, respectively. The differences between the target element concentration values per samples are available, too. In this respect, the distances between the other samples, with defined concentration values,

Variogram, Fig. 2 Variogram calculation process

are also calculated. Having all these details, variogram is generated using the equation below (David 1982; Isaaks and Srivastava 1990; Journel and Huijbregts 2004; Chilès and Delfiner 2012; Pyrcz and Deutsch 2014):

$$\gamma(h) = \frac{1}{2N(h)} \sum_{i=1}^{N(h)} [(Z(x_i) - Z(x_{i+h}))^2]$$

where $N(h)$ is the number of sample pairs with h distance (lag distance) from each other. $Z(x_i)$ and $Z(x_{i+h})$ are also the variables with the same distance of h . $\gamma(h)$ represents semi-variograms, generally called variograms in literature although it is half of a variogram, in actuality.

Variogram is generally a tool to evaluate the dissimilarity of a quantitative value, i.e., a local variable, between two samples with h distance. In most of the mineral deposits, such local variables are represented as element concentrations.

Figure 3 simply demonstrates the variogram's structure. In most of the mineralization and mineral deposits, variogram does not start from 0, i.e., the variance is not zero. Such a difference is called the “nugget effect” (Bohling 2005). In general, the nugget effect represents any discontinuities at the origin, even with different causes. It happens due to some reasons as the sources of variance such as (Chilès and Delfiner 2012):

- A structure, microstructure, or “geological noise”; it happens when the range is less than the distance between the samples in sampling network.
- Measurement or positioning errors.

Variogram, Fig. 3 Schematic variogram and its representative parts

Variogram, Fig. 4 Various main types of variograms

The variogram fitted to the points often inclines gently until it reaches the sill, i.e., variance. Such a distance is called “range,” which represents the maximum distance between the samples in which they spatially affect each other, i.e., their covariance is zero.

Main Types of Variogram

In order to evaluate variograms, we need to study the standard variograms rather than the experimental ones. The main standard variogram types are (Fig. 4) (Remy et al. 2009):

1. Spherical variogram (Matheron 1963):

$$\gamma(h) = \begin{cases} 0 & ; h = 0 \\ c \cdot \left(1.5 \left(\frac{\|h\|}{a} \right) - 0.5 \left(\frac{\|h\|}{a} \right)^3 \right) & ; \|h\| \leq a \\ c & ; h > a \end{cases}$$

where c represents the difference between the nugget effect and the sill, a is the range, and h is the lag. This equation is

Variogram, Fig. 5 Schematic explanation of the experimental variogram tolerance

applicable when the nugget effect is zero; however, in case it is not, we need to add its value to the equation. This variogram is the most useful variogram in geostatistics.

2. Exponential variogram:

$$\gamma(h) = c. \left(1 - \exp\left(\frac{-3\|h\|}{a}\right) \right)$$

3. Gaussian variogram:

$$\gamma(h) = c. \left(1 - \exp\left(\frac{-3\|h\|^2}{a^2}\right) \right)$$

The covariance equivalent of the above models is defined as (Remy et al. 2009):

$$C(h) = C(0) - \gamma(h), \text{ with } C(0) = 1$$

It is always advised to generate several variograms with different dip and azimuth values to define the optimum values of sill and range using different available scenarios (Deutsch and Journel 1998; Remy et al. 2009; Sadeghi 2020). It helps with the evaluation of the experimental variogram tolerance (Fig. 5). In other words, variogram is calculated per principal direction after any coordinate and data transformation step. Such directions are represented by azimuth and dip angles. The final variogram tolerance is demonstrated in Fig. 5.

Generally, in fitting any types of the abovementioned variograms, one condition should be taken into consideration (Goovaerts 1997; Remy et al. 2009):

$$\text{Nugget effect} + \text{sill} = 1$$

In case we face zonal mineralization, the variogram could have more than a single structure. In other words, it can have one nugget effect but several sills and ranges. Each structure could have its own individual type of variogram. However, again the sum of the nugget effect and all the sill values together should be 1 while fitting the variogram.

Summary and Conclusions

In projects such as mineral or petroleum exploration, the limited number of relevant geological samples on or under the ground has been always critical. This is because of some reasons such as lack of access to some areas, limited budget for further sampling and analysis, and of course limited time for further sampling and analysis. To study of the sample values as the representatives for sampled and unsampled areas, interpolation techniques such as IDW and various types of kriging have been developed and applied to generate estimated models and provide a better view of the

mineralization and spatial continuity and connectivity of the sample data values. In order to apply the kriging interpolation method and, through that, quantify the errors related and the probabilities required for spatial and stochastic uncertainty quantification, (semi-)variograms have been introduced and applied as the main tools. Using variograms and variography, the range that samples can affect each other spatially is calculated. The samples located in the same range will only be used for the interpolations. Such variograms can be studied in various azimuths and dips (e.g., 0, 45, 90, 135, and 180) to provide optimum values of the sill, the nugget effect, range, and other required statistics. Then, the interpolated models will be generated based on such calculated values. Such details are also applied to simulate more than one scenario (i.e., realization) based on the same datasets, to provide both Bayesian and frequency frameworks and calculate the stochastic and spatial uncertainties – see the entries “Uncertainty Quantification” and “Simulation.”

Definition

Very fast simulated reannealing (VFSR) is an improved version of simulated annealing (SA). The latter is a global optimization method suitable for complex, non-convex problems. It aims to optimize an objective function $\mathcal{H}(\mathbf{x})$, with respect to the D -dimensional parameter vector $\mathbf{x} = (x_1, \dots, x_D)^T$. Simulated annealing relies on random Metropolis sampling of the parameter space which mimics the physical annealing process of materials. The annealing algorithm treats $\mathcal{H}(\mathbf{x})$ as a fictitious energy function. The algorithm proposes moves which change the current state $\mathbf{x}$, seeking for the optimum state. The proposed states are controlled by an internal parameter which plays the role of temperature and controls the acceptance rate of the proposed states.

Very fast simulated reannealing employs a fast temperature reduction schedule in combination with periodic resetting of the annealing temperature to higher values. In addition, it allows different temperatures for different parameters, and an adaptive mechanism which tunes temperatures to the sensitivities of the objective function with respect to each parameter. These improvements allow fast convergence of the algorithm to the global optimum. For reasons of conciseness and without loss of generality, it is assumed in the following that the optimization problem refers to the *minimization* of the objective function $\mathcal{H}(\mathbf{x})$.

Overview

Annealing is a physical process which involves heat treatment and is used in metallurgy to produce materials (e.g., steel) with improved mechanical properties. It was presumably crucial in the manufacturing of Damascus steel swords which were famous in antiquity for their toughness, sharpness, and strength. The well-kept secrets of Damascus sword-making were lost in time as the interest in swords as weapons waned. However, their legend survived in popular culture,

inspiring the references to “Valyrian steel” in the popular *Game of Thrones* saga. The secrets of the long-lost art were presumably re-discovered in 1981 by Oleg D. Sherby and Jeffrey Wadsworth at Stanford University. A key factor for the effectiveness of annealing is the heating process which enables the material to escape metastable atomic configurations (corresponding to local optima of the energy) and to find the most stable configuration that corresponds to the global minimum of the energy.

Simulated annealing (SA) is a stochastic optimization algorithm developed by Scott Kirkpatrick and co-workers. It uses randomness in the search for the global minimum of $\mathcal{H}(\mathbf{x})$. The randomness is introduced through (i) a proposal distribution which generates new proposal states $\mathbf{x}_{\text{new}}$ of the parameter vector and (ii) through probabilistic decisions whether to accept or reject the proposal states. In contrast, in deterministic optimization methods, every move is fully determined from the current state and the properties of the objective function.

Simulated annealing belongs in a class of models inspired by physical or biological processes; these algorithms are known as *meta-heuristics* (see Ingber (2012) and references therein.) Physical annealing involves a heat treatment process which in SA is simulated using the Metropolis Monte Carlo algorithm (Metropolis et al. 1953). At every iteration of the SA algorithm, a random solution (state) $\mathbf{x}_{\text{new}}$ is generated for the parameters by local perturbation of the current state $\mathbf{x}_{\text{cur}}$. The proposed state is accepted and becomes the new current state according to an acceptance probability; the latter depends on the value of $\mathcal{H}(\mathbf{x}_{\text{new}})$ compared to $\mathcal{H}(\mathbf{x}_{\text{cur}})$ and an internal SA “temperature” variable T . The new state is accepted if the proposal lowers the objective function. On the other hand, even states $\mathbf{x}_{\text{new}}$ such that $\mathcal{H}(\mathbf{x}_{\text{new}}) > \mathcal{H}(\mathbf{x}_{\text{cur}})$ are assigned a non-zero acceptance probability which is higher for higher temperatures.

The SA temperature is initially set to a problem-specific, user-defined high value which allows higher acceptance rates for sub-optimal states. This choice helps the algorithm to effectively explore the parameter space because it allows escaping from local minima of the objective function. The temperature is then gradually lowered in order to “freeze” the system in the minimum energy state. The function $T(k)$, where k is an integer index, describes the evolution of temperature as a function of the “annealing time” k and defines the *SA cooling schedule*. This should be carefully designed to allow convergence of the algorithm to the global minimum (Geman and Geman 1984; Salamon et al. 2002).

SA can be applied to objective functions with arbitrary nonlinearities, discontinuities, and noise. It does not require the evaluation of derivatives of the objective function, and thus it does not get stuck in local minima. In addition, it can handle arbitrary boundary conditions and constraints imposed on the objective function. On the other hand, SA requires

tuning various parameters, and the quality of the solutions practically achieved by SA depends on the computational time spent. SA provides a statistical guarantee for finding the (global) optimal solution, provided the correct combination of *state proposal (generating) distribution* and cooling schedule are used (Ingber 2012). The convergence of the algorithm is based on the weak ergodic property of SA which ensures that almost every possible state of the system is visited. Achieving the statistical guarantee can in practice significantly slow down classical SA, since a very gradual cooling schedule is required. To reduce the computational time, often a fast temperature reduction schedule is applied, i.e., $T(k+1) = cT(k)$, where $0 < c < 1$, which amounts to *simulated quenching (SQ)* of the temperature. However, this exponential cooling schedule does not guarantee convergence to the global optimum.

Very fast simulated reannealing (VFSR) is also known as adaptive simulated annealing (ASA) (Ingber 1989, 2012). ASA is the currently preferred term, while VFSR was used initially to emphasize the fast convergence of the method compared to the standard Boltzmann annealing approach. ASA employs a generating probability distribution for proposal states which allows an optimal cooling schedule. This setup enables the algorithm to explore efficiently the parameter space. *Reannealing* refers to a periodical resetting of the temperature to higher (than the current) value after a number of proposal states have been accepted. Then, the search begins again at the higher temperature. This strategy helps the algorithm to avoid getting trapped at local minima. Finally, ASA allows for different temperatures in each direction of the parameter space. The parameter temperatures determine the width of the generating distribution for each parameter, thus enabling *the cooling schedule to be adapted* according to the sensitivity of the objective function in each direction. ASA maintains SA's statistical guarantee of finding the global minimum for a given objective function, but it also features significantly improved convergence speed. It has been demonstrated that ASA is competitive with respect to other non-gradient-based global optimization methods such as genetic algorithms and Taboo search (Chen and Luk 1999; Ingber 2012).

Methodology

The SA algorithm is a method for global – possibly constrained – optimization of general, nonlinear, real-valued objective functions $\mathcal{H}(\mathbf{x})$ where $\mathbf{x} \in \chi \subset \mathbb{R}^D$ is a vector of parameters that takes values in the space χ :

$$\mathbf{x}^* = \arg \min_{\mathbf{x} \in \chi} \mathcal{H}(\mathbf{x}), \text{ potentially with constraints on } \mathbf{x}.$$

The standard SA algorithm is based on the Markov chain Monte Carlo method (Geman and Geman 1984). It involves homogeneous Markov chains of finite length which are generated at progressively lower temperatures. The following parameters should thus be specified: (i) A sufficiently high initial temperature T_0 ; (ii) a final “freezing” temperature T_f (alternatively a different stopping criterion); (iii) the length of the Markov chains; (iv) the procedure for generating a proposal state $\mathbf{x}_{\text{new}}$ “neighboring” the current state $\mathbf{x}_{\text{cur}}$; (v) the acceptance criterion which determines if the proposal state $\mathbf{x}_{\text{new}}$ is admitted; and (vi) a rule for temperature reduction (annealing schedule).

Boltzmann Simulated Annealing

The SA algorithm is initialized with a guess for the parameter vector $\mathbf{x}_0$. The simulation proceeds by iteratively proposing new states $\mathbf{x}_{\text{new}}$ based on the *Metropolis algorithm* (Metropolis et al. 1953). These proposal states are generated by perturbing the current state $\mathbf{x}_{\text{cur}}$. For example, in Boltzmann annealing, this can be done by drawing the proposal state $\mathbf{x}_{\text{new}}$ from the proposal distribution

$$g(\mathbf{x}_{\text{new}}|\mathbf{x}_{\text{cur}}) = \frac{1}{(2\pi T)^{D/2}} \exp\left[-\|\mathbf{x}_{\text{new}} - \mathbf{x}_{\text{cur}}\|^2 / 2T\right].$$

For every proposed move, the difference $\Delta\mathcal{H} = \mathcal{H}(\mathbf{x}_{\text{new}}) - \mathcal{H}(\mathbf{x}_{\text{cur}})$ between the current state, $\mathbf{x}_{\text{cur}}$, and the proposed state, $\mathbf{x}_{\text{new}}$, is evaluated. If $\Delta\mathcal{H} < 0$, the proposed state is accepted as the current state. On the other hand, if $\Delta\mathcal{H} > 0$, the acceptance probability is given by the exponential expression $P_{\text{acc}} = 1/[1 + \exp \Delta\mathcal{H}/T]$ (Salamon et al. 2002; Ingber 2012). The decision whether to accept $\mathbf{x}_{\text{new}}$ is implemented by generating a random number $r \sim U(0, 1)$ from the uniform distribution between 0 and 1; if $r \leq P_{\text{acc}}$, the proposed state is accepted ($\mathbf{x}_{\text{cur}}$ is updated to $\mathbf{x}_{\text{new}}$), otherwise the present state is retained as the current state.

The above procedure is repeated a number of times before the temperature is lowered. The *acceptance rate* is equal to the percentage of proposal states that are accepted. The initial temperature is selected to allow high acceptance rate (e.g., $\approx 80\%$) so that the algorithm can move between different local optima. The temperature reduction is determined by the *annealing schedule* which is a key factor for the performance of the SA algorithm.

The annealing schedule depends on the form of the generating function used: to ensure that the global minimum of $\mathcal{H}(\mathbf{x})$ is reached, it must be guaranteed that all states $\mathbf{x} \in \chi$ can be visited an infinite number of times during the annealing process. In the case of Boltzmann annealing, this condition

requires a cooling schedule no faster than logarithmic, i.e., $T_k = T_0 \ln k_0 / \ln k$, where $k_{\max} \geq k \geq k_0$. The integer index k counts the simulation *annealing time* and $k_0 > 1$ is an arbitrary initial counter value (Ingber 2012). The final temperature, $T_{k_{\max}}$, should be low enough to trap the objective function in the global optimum state.

Fast (Cauchy) Simulated Annealing

Boltzmann SA requires a slow temperature reduction schedule as determined by the logarithm function. In practical applications, an *exponential schedule* $T_{k+1} = cT_k$ where $0 < c < 1$ is often followed. However, this fast temperature reduction enforces *simulated quenching* which drives the system too fast toward the final temperature. The exponential annealing schedule offers computational gains, but it does not fulfill the requirement of weak ergodicity (infinite number of visits to each state). Hence, it does not guarantee convergence of SA to the global minimum.

A *fast annealing* schedule which lowers the temperature according to $T_k = T_0/k$ is suitable for the *Cauchy generating distribution*:

$$g(\mathbf{x}_{\text{new}}|\mathbf{x}_{\text{cur}}) = \frac{T}{(\|\mathbf{x}_{\text{new}} - \mathbf{x}_{\text{cur}}\|^2 + T^2)^{(D+1)/2}}.$$

Fast cooling works in this case due to the “heavy tail” of the Cauchy distribution which carries more weight in the tail than the Gaussian distribution used in Boltzmann SA (Ingber 2012; Salamon et al. 2002). The resulting higher probability density for proposal states considerably different than the current state allows the algorithm to visit efficiently all the probable states in the parameter space.

Very Fast Simulated Reannealing

ASA includes three main ingredients similar to classical annealing: the generating distribution of proposal states, the acceptance probability, and the annealing schedule. ASA uses an *acceptance temperature* $T_{\text{acc}}(k_a)$ which controls the acceptance rate of proposed moves and a set of D temperatures $\{T_i(k_i)\}_{i=1}^D$ which control the width of the generating distribution for each parameter individually.

In addition to these three ingredients, ASA includes a *reannealing scheme* which rescales all the temperatures after a certain number of steps so that they adapt to the current state of $\mathcal{H}(\mathbf{x})$. Reannealing adjusts the rate of change of the annealing schedule independently for each parameter. This helps the algorithm adapt to changing sensitivities of the objective function as

it explores the parameter space, encountering points (in D -dimensional space) with very different local geometry, where $\mathcal{H}$ may change rapidly with respect to some parameters but considerably more slowly with respect to others. The main steps of ASA are outlined in the text below and in Algorithm 1.

Generation of proposal states: If the parameters x_i are constrained within $[A_i, B_i]$, where A_i and B_i are, respectively, the lower and upper bounds, the ASA proposal states are generated by means of the following steps (Ingber 1989; Chen and Luk 1999; Ingber 2012):

$$\mathbf{x}_{\text{new}} = \mathbf{x}_{\text{cur}} + \Delta \mathbf{x}, \quad (1a)$$

$$\Delta x_i = y_i(B_i - A_i), \quad i = 1, \dots, D, \quad (1b)$$

$$y_i = \text{sign}\left(u_i - \frac{1}{2}\right) T_i(k_i) \left[\left(1 + \frac{1}{T_i(k_i)}\right)^{|2u_i-1|} - 1 \right] \quad (1c)$$

$$\text{where } u_i \sim U[0, 1], \quad (1d)$$

is a random variable uniformly distributed between zero and one. Consequently, the random variable y_i is centered around zero and takes values in the interval $[-1, 1]$. The integer indices k_i are used to count time. Certain values of y_i can yield proposed parameters outside the range $[A_i, B_i]$; these values should be discarded (Ingber 1989). Lower values of temperature force y_i to concentrate around zero, while high temperature values lead to an almost uniform distribution of y_i between -1 and 1 .

Acceptance probability: The *acceptance probability* of a proposed state is given by (Chen and Luk 1999)

$$P_{\text{acc}} = \frac{1}{1 + e^{\Delta \mathcal{H}/T_{\text{acc}}(k_a)}}. \quad (2)$$

In Eqs. (1) and (2), the set of integer indices $\{k_i\}_{i=1}^D \cup \{k_a\}$ represents different *annealing times*. ASA uses one time index per parameter, so that the reannealing process can adjust the annealing time differently for each parameter. This multi-dimensional annealing schedule enables adaptation of the proposal states to different sensitivities of $\mathcal{H}(\mathbf{x})$ with respect to the parameters x_i , $i = 1, \dots, D$.

Reannealing: Every time a number N_{acc} of proposal states have been accepted, *reannealing* is performed. This procedure adjusts the annealing temperatures and times to the local geometry of the parameter space. The *sensitivities* $\{s_i\}_{i=1}^D$ are calculated as follows:

$$s_i = \left| \frac{\partial \mathcal{H}(\tilde{\mathbf{x}})}{\partial x_i} \right| \approx \left| \frac{\mathcal{H}(\tilde{\mathbf{x}} + a\hat{\mathbf{e}}_i) - \mathcal{H}(\tilde{\mathbf{x}})}{a} \right|, \quad i = 1, \dots, D, \quad (3)$$

Very Fast Simulated Reannealing,

Algorithm 1 ASA main steps.

The integers n and N count the accepted and generated states, respectively. N_s : # proposed states between annealing steps. N_{acc} : # accepted proposals between reannealing steps.

Input: Initialize: $\mathbf{x}_0 \in \mathcal{X}$, $T_{acc}(0) \leftarrow \mathcal{H}(\mathbf{x}_0)$, $k_i \leftarrow 1$, $k_a \leftarrow 1$, $\mathbf{x}_{cur} \leftarrow \mathbf{x}_0$, $T_i(0) \leftarrow 1$, $n \leftarrow 0$, $N \leftarrow 0$

```

1 while termination condition is not met do Annealing loop
2   Generate proposal state  $\mathbf{x}_{new}$  using Eq. (1) ;
3    $N \leftarrow N + 1$  (increase generated states counter) ;
4   if  $\mathcal{H}(\mathbf{x}_{new}) < \mathcal{H}(\mathbf{x}_{cur})$  then Update current state
5     |  $\mathbf{x}_{cur} \leftarrow \mathbf{x}_{new}$ ;  $n \leftarrow n + 1$  (increase accepted states counter)
6   else
7     | Calculate acceptance probability  $P_{acc}$  from Eq. (2) ;
8     | if  $P_{acc} > r \sim U(0, 1)$  then Update current state
9     | |  $\mathbf{x}_{cur} \leftarrow \mathbf{x}_{new}$ ;  $n \leftarrow n + 1$  (increase accepted states counter)
10    | end
11  end
12  if  $n > N_{acc}$  then
13    | Reannealing based on Eqs. (3)-(5) ;
14    |  $n \leftarrow 0$  (reset accepted states counter)
15  else
16    | Go to Step 2
17  end
18  if  $N > N_s$  then
19    | Annealing based on Eqs. (6) ;
20    |  $N \leftarrow 0$  (reset generated states counter)
21  end
22 end

```

where $\tilde{\mathbf{x}}$ is the *current optimal parameter vector*, a is a small increment, and $\hat{\mathbf{e}}_i$ is a D -dimensional unit vector in the i -th direction of parameter space, i.e., $\{\hat{\mathbf{e}}_i\}_k = \delta_{i,k}$ ($\delta_{i,k} = 1$ for $i = k$ and $\delta_{i,k} = 0$ for $i \neq k$ being the Kronecker delta).

Reannealing adjusts the temperatures and annealing times as follows ($\leftarrow$ implies assignment of the value on the right side of $\leftarrow$ to the variable appearing on the left side)

$$T_i(k_i) \leftarrow \frac{s_{\max}}{s_i} T_i(k_i), \quad s_{\max} = \max_{i=1, \dots, D} s_i, \quad (4a)$$

$$k_i \leftarrow \left\lceil \frac{1}{c} \log \left(\frac{T_i(0)}{T_i(k_i)} \right) \right\rceil^D, \quad i = 1, \dots, D, \quad (4b)$$

where $c > 0$ is a user-defined parameter that adjusts the rate of reannealing and $T_i(0)$ is usually set to unity (Chen and Luk 1999).

Similarly, the acceptance temperature is rescaled according to

$$T_{acc}(k_a) \leftarrow \mathcal{H}(\tilde{\mathbf{x}}), \quad T_{acc}(0) \leftarrow \mathcal{H}(\mathbf{x}_a), \quad (5a)$$

$$k_a \leftarrow \left\lceil \frac{1}{c} \log \left(\frac{T_{acc}(0)}{T_{acc}(k_a)} \right) \right\rceil^D, \quad (5b)$$

where $\mathbf{x}_a$ is the *last accepted state*.

The reannealing procedure enables ASA to decrease the temperatures T_i along the high-sensitivity directions of $\mathcal{H}(\mathbf{x})$, thus allowing smaller steps in these directions, and to increase T_i along the low-sensitivity directions, thus allowing larger jumps.

Annealing: After a number of steps N_s have been completed, the *annealing* procedure takes place. The annealing times increase by one, and the annealing temperatures are modified according to Eq. (6). The annealing schedules for the temperature parameters follow the stretched exponential expression

$$\begin{aligned} T_{\text{acc}}(k_a) &= T_{\text{acc}}(0) \exp\left(-ck_a^{1/D}\right), \\ T_i(k_i) &= T_i(0) \exp\left(-ck_i^{1/D}\right), i = 1, \dots, D, \end{aligned} \quad (6)$$

where $T_i(k_i)$ is the current temperature for the i -th parameter (Ingber 1989).

Termination: The above operations are repeated until the algorithm terminates. Different termination criteria can be used in ASA depending on the available computational resources and a priori knowledge of $\mathcal{H}$. Such criteria include the following: (i) an average change of $\mathcal{H}(\mathbf{x})$ (over a number of accepted proposal states) lower than a specified tolerance; (ii) exceedance of a maximum number of iterations (generated proposal states); (iii) exceedance of a maximum number (usually proportional to D) of $\mathcal{H}$ evaluations; (iv) exceedance of a maximum computational running time; and (v) attainment of a certain target minimum value for $\mathcal{H}$.

Initialization: An initial value, $T_{\text{acc}}(0)$, should be assigned to the acceptance parameter. One possible choice is to set $T_{\text{acc}}(0) = \mathcal{H}(\mathbf{x}_0)$ where $\mathbf{x}_0$ is the random initial parameter vector (Chen and Luk 1999). A more flexible approach matches $T_{\text{acc}}(0)$ with a selected acceptance probability, e.g., $P_{\text{acc}} = 0.25$ (Iglesias-Marzoa et al. 2015). The optimal values of N_s and N_{acc} do not seem to depend crucially on the specific problem (Chen and Luk 1999). Often an adequate choice for N_{acc} is on the order of tens or hundreds and for N_s on the order of hundreds or thousands. Higher values may be necessary to adequately explore high-dimensional and topologically complex parameter spaces. A good choice for the annealing rate control parameter is $c \approx 1 - 10$. In general, higher values lead to faster temperature convergence at the risk that the algorithm may get stuck near a local minimum. Lower values lead to slower temperature reduction and therefore increase the computational time. Given ASA's adaptive ability, the choices for c , N_{acc} , N_s do not critically influence the algorithm's performance but they have an impact on the computational time. For problems where ASA is used for the first time, it is a good idea to experiment with different choices (Iglesias-Marzoa et al. 2015).

Applications

An introduction to SA for spatial data applications is found in Hristopulos (2020). Geostatistical applications are reviewed in Pyrcz and Deutsch (2014). An informative review of ASA (VFSR) is given in Ingber (2012), while a mathematical treatment of SA is presented in Salamon et al. (2002). ASA has been successfully used for geophysical inversion (Sen and Stoffa 1996). The ASA algorithm and its application in various signal processing problems are reviewed in Chen and Luk (1999). A detailed investigation of ASA's application for

determining the radial velocities of binary star systems and exoplanets is given in Iglesias-Marzoa et al. (2015).

Software Implementations

In Matlab, SA is implemented by means of the command `simulannealbnd`. In R, the packages `optimization` and `optim_sa` provide SA capabilities. In Python, this functionality can be found in the `scipy.optimize` module. A C-language code for ASA (VFSR) developed by Lester Ingber is available from his personal website.

Summary and Conclusions

ASA (VFSR) is a computationally efficient implementation of the simulated annealing algorithm which employs a fast (stretched-exponential) annealing schedule in combination with a reannealing program which periodically resets the temperature. ASA is an adaptive algorithm: both the annealing and reannealing schedules take into account the sensitivity of the objective function in different directions of parameter space. Thanks to this adaptive ability, ASA is an effective stochastic global optimization method which has been successfully applied to complex, nonlinear objective functions that may involve many local minima. Estimates of parameter uncertainty can be obtained by means of the Fisher matrix and Markov chain Monte Carlo methods.

ASA converges faster than the classical SA algorithm, it allows each parameter to adapt individually to the local topology of the objective function, and it involves a faster schedule for temperature reduction (Iglesias-Marzoa et al. 2015). The counterbalance of these advantages is that ASA is more complex than the classical SA algorithm, it involves more internal parameters, and the stretched exponential expression for temperature reduction requires using double precision arithmetic and checking of the exponents to avoid numerical problems. Overall, ASA has found several applications in the geosciences (Sen and Stoffa 1996; Pyrcz and Deutsch 2014; Hristopulos 2020).

Electronic City, Bangalore, Karnataka, India

Definition

While data visualization is widely used for exploring and visually comprehending the data, virtual reality (VR) takes it to a higher level of immersive experience. VR provides an artificially simulated environment in which the user can be part of the environment and interact with it, as permitted by the VR application. VR has been used as an extension to several graphical user interface (GUI) applications, but one of the most relevant applications is representing the three-dimensional (3D) model of the planet Earth itself. This 3D representation of the Earth extends to a four-dimensional (4D) one whenever spatiotemporal data is used. Such an application allows the user to explore and experience the environment and to edit the data loaded to visualize the world, representing the natural and man-made artifacts. Such a VR application is referred to as the *virtual world*

(Yu and Gong 2012). An example of a virtual globe that has popularized this technology in recent times is the Google Earth VR.¹

Overview

The history of virtual globes is not very old. The Geoscope was built as a large spherical display that entailed modeling and simulating a virtual environment of the Earth using computers, by the architect Buckminster Fuller in the 1960s (Yu and Gong 2012). This is considered as the early beginnings of the virtual globe. This has been further conceptualized by Al Gore in the early 1990s as the “Digital Earth” to serve as a digital access point for massive scientific as well as human-centric data. After a hiatus, by the late 1990s, the advent of high-performance graphics processor unit (GPU) technology, availability of high-resolution satellite images, and high-speed Internet connectivity paved the way to actual implementations of the virtual globes. The popular virtual globes released by the prominent technology as well as space organizations include the Encarta Virtual Globe 98 and Bing Maps Platform (Microsoft), 3D World Atlas (Cosmi), WorldWind (NASA), Google Earth (Google), and ArcGIS Explorer (ESRI). There are also several free virtual globe software, such as Earth3D and Marble, where the latter is open source too.

The virtual globe must be distinguished from a data visualization tool with a GUI involving 3D rendering of the globe. An example of such a browser-based visualization tool with 3D animated map for visualization of global weather conditions is the Earth Nullschool.² While a virtual globe is a special visualization tool of the planet, all visualization tools depicting the Earth cannot be considered as virtual globes. This is because virtual globes involve VR where the user is *immersed* in the virtual environment, which is achieved by using simulations of the camera orientation and position in the graphical application. The virtual globes have also been referred to as “geobrowsers” (Yu and Gong 2012) owing to their function of exploring the Earth, which is analogous to the exploration of the Internet by the Web browsers.

In a virtual globe, the worldwide geographic maps can be graphically rendered using different viewpoints and geographical projection systems (Yang et al. 2018). It can be set up in one of the four ways – (i) the conventionally used exocentric 3D globe, where the viewer sees from outside of the globe; (ii) a 2D flat map of the globe projected onto a plane; (iii) an egocentric 3D globe, where the viewer is immersed in the environment; or (iv) a curved map of the

¹<https://arvr.google.com/earth/>

²<https://earth.nullschool.net/about.html>

globe. The curved map is a projection on a section of a sphere, giving the appearance of an opera stage or a theater. Extensive user study has shown that the most accurate responses in the analytical tasks using the virtual globe, as well as in direction estimation, have been obtained in the case of the exocentric virtual globe. Motion sickness is a known issue users face in VR applications. The user study also revealed that the motion sickness was least felt in the cases of exocentric globe and flat maps. Exocentric globe, where the viewer sees the world as from space, is the most intuitive, and egocentric globe, where the viewer is in the center of the sphere, which renders the globe in its inner concave walls, is the least intuitive. The egocentric view provided the best immersive experience, but the perceptual distortion of the familiar convex (spherical) globe to concave walls made it a poor choice for this specific VR application. Similarly, the flat map using Hammer map projection, i.e., equal-area projection, has been found to be a better fit for VR application compared to the spherical projection used in curved map. This study has been conducted using head-mounted displays (HMDs).

HMDs and controllers are important accessories for virtual globes, and the technologies supported by the VR application are critical for its usability, e.g., Google Earth VR supports HMDs from HTC Vive and Oculus Rift, which are widely used HMDs. Figure 1 shows how an HMD and a hand controller are used for different settings of the Google Earth VR application.

Applications

Google Earth itself has served several purposes since its release in 2005 (Yu and Gong 2012). It has been instrumental in supporting and advancing scientific research in the different domains, such as earth observations, natural hazards, human geography, etc. It has provided services for data visualization, collection, validation, integration, dissemination, modeling, and exploration and also as a decision support system. Its merits include the following: (i) support for global-scale research owing to the access to global data acquired from high-resolution satellite imaging, aerial imagery, etc., through the use of a single coordinate system, i.e., the World Geodetic System of 1984 data, and (ii) browser-based easy-to-use visualization through the use of WebGL. Studying the evolution of Google Earth points to a few pertinent gaps to be addressed to improve the uptake in the usability of virtual globes. These include the data inconsistency issue of nonuniform precision of satellite imaging and other Earth observation data; limited interoperability of the digital elevation model with other high-resolution topography data, e.g., acquired using Light Detection and Ranging (LiDAR) sensors (Bernardin et al. 2011); and limited flexibility in analytical functionality when using specific file

format, i.e., Keyhole Markup Language (KML), Web services, and API or software development kit (SDK), e.g., NASA WorldWind.

The learnings from the Google Earth project have been incorporated in the making of the Google Earth VR, which is a relatively modern virtual globe, launched in late 2016 (Käser et al. 2017). In addition to the features to scale-and-fly, search, rotate, and teleport using the HMD and controllers (Fig. 1), Google Earth VR also provides haptics and sound effects, e.g., when using the 3D Cone Drag gesture to grab the planet itself, the user can feel and hear the static friction that the Earth exhibits. In terms of performance, despite the requirement to render trillions of triangles in the data, Google Earth VR with both hardware (GPU) and software optimizations provides 90 fps (frames per second), which is a requirement for VR.

The improved user interactivity of the virtual globe has found itself an application in facilitating public participation in an urban planning project (Wu et al. 2010). In an example where Google Earth is used as the virtual globe application, a distributed system has been designed to display urban planning information gathered from the virtual globe and to facilitate discussion forums between urban planning designers and the general public. The general public can explore the relevant geospatial data from a macro- to a micro-spatial scale, where the latter is the street scale. The architecture for such a distributed system has been possible by using the Web Service technology, namely, Service-Oriented Architecture (SOA) integrated with a virtual globe, which is now treated as a Web Service. It has three layers, namely, the support, the service, and the client layers. Such a system has enabled the public to inspect an urban planning project at their own convenience and provide feedback to the planners. Additionally, the application uses interoperable CityGML, a standard descriptive language for city models, which improves the system extensibility. However, this also requires appropriate system capability to reduce network latency issues incurred owing to transfer of large XML files in CityGML. Overall, this example shows how virtual globes can be relevant when integrated with other systems for pertinent applications.

Demonstrating the diversity in applications, Crusta is an example of virtual globe to visualize planetary scale topography for geological studies (Bernardin et al. 2011). Crusta has been proposed to address the challenges in visualization of digital elevation models (DEMs) of high spatial resolution of $0.5\text{--}1\text{ m}^2$ per sample and large extent ($>2000\text{ km}^2$). The globe is geometrically rendered using a 30-sided polyhedron, defined by base patches, that can be subdivided into different resolutions in a pyramidal format. The subdivision is allowed to accommodate input data of varying resolutions, including global (BlueMarble by NASA) and local (acquired using tripod LiDAR) spatial scales. The use of the polyhedron resolves the issue of “pinching” or distortion at the poles.

Virtual Globe, Fig. 1 Examples of the usage of head-mounted display (HMD) and hand controller by a viewer in a virtual globe application, namely, the Google Earth VR, and its corresponding visualizations. (Image courtesy: <https://arvr.google.com/earth/>)

Crusta implements dynamic shading for its graphical rendering, which has clearly revealed the previous ruptures along the Owens Valley fault in Eastern California. One of the strengths of Crusta has been in providing visualizations with high-resolution topographic detail along with the shading and exaggeration of the topography, in addition to the vertical exaggeration that all virtual globes provide. This is a use case of virtual globes for geological exploration and knowledge discovery.

Archaeology is an area where virtual globes has practical applications, as they help to preserve fragile artifacts by its remote exploration without the physical presence of human beings. Archaeological data involves spatiotemporal information and hence is 4D (De Roo et al. 2017). The usability test of extending the application of a 3D virtual globe to a 4D archaeological geographical information system (GIS) has revealed its feasibility for the same. Testing the application on five archaeologists with a scenario of excavation site of Kerkhove, Belgium, has shown that the 4D virtual globe can be used for fieldwork preparation, report generation, and communication by knowledge sharing on the Internet. While the spatial and temporal dimensions have been decoupled to a larger extent in its treatment in this specific application, there is scope for tighter coupling between the two to improve querying as well as simulation in the combined 4D space. Altogether, virtual globes can be used in archaeology for site exploration, as well as for gaining insights to the site evolution using 4D GIS.

A similar use case of 4D geospace in virtual globe is in visualizing and assessing geohazards (Havenith et al. 2019). The requirement here for assessment and analysis of spatiotemporal phenomena, namely, geohazards, is to have a combination of GIS, and geological modeling, supplemented by interactive tools, such as the freely available Google Earth. Virtual geographic environments (VGEs) have been originally conceptualized and implemented to provide multi-dimensional spatiotemporal geographic analysis along with real-time collaboration between geoscientists. However, the relatively low contributions by geoscientists to build VGEs had not led to the intended fluid interactions and results sharing, despite the presence of collaborative virtual environments (CVEs). In the past, CVEs had been effectively used for collaborative visualization and analysis of geospatial data, using mapping elements, interactive cooperative work, and semiotics. In this backdrop, the development of VR has now allowed immersive visualization, thus adding a new dimension to the VGEs. The increased commoditization and advent of low-cost VR technology has promoted the use of virtual globes as a VGE. In addition to geological applications, e.g., Crusta, the virtual globes can now be extended with numerical models to simulate, visualize, and analyze natural hazards, such as dam breaks, rock falls, etc. Such a system requires combining large-scale high-resolution geophysical-

geological data, DEMs, textures from remote imagery, etc. and visualization support, such as 3D stereo-visualization with HMD for VR. While there is scope for extending Google Earth VR to studying geohazards, there is now the need for integrating more compute resources to solve numerical models, along with maintaining the frame rate of 90 fps for rendering in VR. As an application dealing with risk assessment, handling the epistemic and total uncertainty in geohazard assessment is a desirable feature in the 4D geospace depicted in virtual globe. Thus, handling uncertainty has to be considered as a future development. Another critical feature of a fully integrated 3D geohazard modeling application is the seamless interoperability of the virtual globe with several decision support systems.

Apart from geospatial applications, virtual environments also play an instrumental role in geo-education (Shakirova et al. 2020). VR is considered one of the effective emerging technologies that can be used in STEM education. An example is the use of virtual globes in geoscience education. A specific study testing the usability of Google Earth VR, Apple Maps (for “visiting” cities), My Way VR (for a virtual journey through countries and cultures), and VR Museum of Fine Arts (for visiting museums), for teaching/learning a physical geography course, has revealed that the experience of using the virtual globes had shifted the aspects of e-learning, such as gamification, interaction, professional activity imitation, etc., from being “desirable” to “expected,” by the students. This shows that the impact of virtual globes has been significant, leading to an increase in demand of its application in e-learning. In addition to developing a pedagogy involving experiences of physical phenomena (climatic changes, natural phenomena) and world tourism, using VR in geo-education provides opportunities for creating content through international educational groups, thus improving the quality of global education. Altogether, the use of more advanced GVEs, through virtual globes, in geo-education promotes geographic research.

Future Scope

While there are specific challenges to be addressed in specialized applications, the future of virtual world technology is in its transition to open-source software (OSS) (Coetzee et al. 2020). Several technologies of virtual world are already available as free applications, for which Google Earth is an example. One step further, NASA WorldWind³ is an example of an open-source virtual globe (Pirotti et al. 2017). WorldWind was originally developed for visualizing the NASA MODIS (Moderate Resolution Imaging Spectroradiometer) land

³<https://worldwind.arc.nasa.gov/about/>

products. It enables visualization of multidimensional data with the help of a framework that uses a digital terrain model (DTM) as its base. It supports several applications involving local communities through GeoWeb 2.0, e.g., exploration of cultural heritage sites, virtual cities to promote world tourism, etc. Just like Google Earth, it was initially freely available, but then it slowly transitioned to open source in the early 2000s. The open source of WorldWind has been available in a variety of programming languages and operating systems – in C# since 2003, in Java since 2006, in Android since 2012, and in JavaScript since 2014. This has been made possible by publishing a SDK that developers can use for building their software for GUIs. These GUIs are developed on the browser increasingly, thus using HTML5 and JavaScript. The SDK supports several file formats for input data, e.g., GeoTIFF, JPG, and PNG formats for raster data, ESRI Shapefiles, KML, and Collada for vector models. It also supports REST, WMS, and Bing Maps services for adding Web Service layers. Releasing the WorldWind software as open source has encouraged the developer community to build several relevant applications, e.g., the Environment Space and Time Web Analyzer (EST-WA) based on netCDF file format, PoliCrowd as a collaborative tourism/cultural heritage platform based on Java, etc. Thus, the evolution of WorldWind in itself and the engagement of larger developer community have extensively promoted the collaborative use of virtual globes in several innovative applications.

One of the near-future goals in terms of improving the usability of virtual globes is to include them in OSGeo (open-source geospatial) software. This can open up further opportunities in benchmarking, technology maturing, and increased uptake in applications worldwide (Coetzee et al. 2020). Overall, the virtual globe continues to be a useful geoscientific exploratory and analytic tool through immersive experience.

Vistelius, Andrey Borisovich

Stephen Henley

Resources Computing International Ltd, Matlock, UK

Fig. 1 Andrey Borisovich Vistelius (1915–1995)

Biography

Andrey Borisovich Vistelius was born in St. Petersburg, Russia, on 7 December 1915. His father Boris Vistelius was a lawyer before the October Revolution of 1917. Boris's father (Andrey's grandfather) was a senior civil servant in the Russian Empire. Relatives of Andrey's mother (the Bogaevsky family) included distinguished academics.

There is no published information on Vistelius' early childhood and how he and his family fared during the

Modified after Henley S. (2018) Andrey Borisovich VISTELIUS. In: Daya Sagar B., Cheng Q., Agterberg F. (eds) *Handbook of Mathematical Geosciences*. revolution and civil war. However, in 1933 Andrey entered Leningrad State University as a student. But in 1935, the family was exiled from Leningrad like many other intellectuals; first to a remote village in middle Russia, later to the city of Samara. As a result, Andrey's education was interrupted. His studies in Leningrad were eventually resumed and in 1939 he graduated brilliantly from the Department of Mineralogy.

Geology and mathematics were his overwhelming passions, with emphasis on practical applications. He was committed to evidence-based science, which in the prevailing atmosphere of "lysenkoism" was a barrier to his career progress.

During World War II, Andrey Vistelius was trapped in besieged Leningrad. He was not enlisted into the army because of poor eyesight. However, his studies continued, with award of his "Candidacy" (equivalent to PhD) in 1941, and Doctor of Science in 1948. He then worked in several state geological organizations, including as director of "expeditions" (responsible for regional geological mapping).

However, to overcome continuing political obstacles, with the support of mathematical Academicians, in 1961 a group headed by Vistelius was set up as the Laboratory of Mathematical Geology within the Leningrad Branch of the Steklov Institute of Mathematics (LOMI) of the USSR Academy of Sciences.

In 1968, he was instrumental, with others, in founding the International Association for Mathematical Geology (IAMG), and was elected its first president. Although the Cold War prevented him from participating in many of IAMG's activities, he continued work as a prolific researcher in Leningrad.

Vistelius' scientific achievements, notably in process modeling and statistical testing of hypotheses against real data were recognized by IAMG, awarding him the Krumbein Medal in 1980 and naming a new award (for young scientists) after him. The Soviet Union authorities rejected this latter proposal on the grounds that such an honor should not be conferred upon a living person, so it was initially designated the President's Award, and changed to the Vistelius Award, as originally intended, after his death in 1995.

In 1987 the Laboratory of Mathematical Geology was transferred to the Institute of Precambrian Geology and Geochronology, as a prelude to its conversion to an Institute in 1991 when the Russian Academy of Natural Sciences (RANS) was founded, and Andrey Vistelius was named an Honorary Member of this Academy.

Andrey Borisovich Vistelius died on 12 September, 1995. He continued to work, lucid and inventive, to the end despite serious illness. In 1992, an English translation of his life's work "Principles of Mathematical Geology" was published (Vistelius 1992) – a reworked version of his Russian monograph published in 1980. Altogether he had more than 200 published works (Henley 2018; Dech and Henley 2003; Romanova and Sarmanov 1970). Dech and Glebovitsky (2000) give a detailed account of the many fields in which the work of Vistelius advanced geological knowledge. A special issue of the *Journal of Mathematical Geology* (volume 35, number 4) in memory of Vistelius was published in 2003 with papers by many of his former colleagues, as well as one previously unpublished paper by Vistelius himself. The breadth of geoscientific subject matter and mathematical approaches shown by this collection of papers is ample illustration of the scientific legacy of Andrey Borisovich Vistelius.

²Albuquerque, NM, USA

Fig. 1 By Grasso Luigi – Own work, CC BY-SA 4.0, <https://commons.wikimedia.org/w/index.php?curid=68766582>

Biography

Geoffrey S. Watson was born in 1921 in Bendigo, a rural community in the state of Victoria, Australia. He was an Australian statistician who spent the majority of his career in North America (USA and Canada), with shorter periods in Australia and the UK. He received a Bachelor of Arts with Honours from the University of Melbourne (1942) and a PhD in statistics from North Carolina State University (1951). He wrote his PhD thesis while visiting Cambridge University in the UK and, while there, he worked with James Durbin of the

London School of Economics. Together they published companion papers in 1950 and 1951 in the journal *Biometrika*, on what is now called the Durbin-Watson statistic. It is used to test the presence of serial correlation in data observed at equal time intervals and is a fundamental component of most time series software packages. Generalizing from time series to spatial data brings attention to the variogram at its closest spatial lag: If this value is small compared to its sill, a null hypothesis of spatial independence is rejected. With fast computing, it is now possible to test for temporal (spatial) independence by computing the statistic for all permutations of the times (locations) of the data; from this null distribution, the percentile of the observed statistic can be obtained.

Geof (as he was known and as he signed his letters) was a quintessential statistical scientist, curious about new ideas in science, with strong mathematical statistical skills and a gift for clear writing in the collaborating discipline. In the geosciences, his most influential work was to help resolve the controversy between “fixism” and “mobilism,” leading up to mobile-plate tectonic theory (continental drift). His research on statistics for directional data on the circle and the sphere allowed hypothesis testing on paleomagnetism of rocks on different sides of the oceans. He is the author of an important monograph, *Statistics on Spheres*, published in 1983. He was also influential in bringing the work of Georges Matheron and his centers of geostatistics and mathematical morphology, located in Fontainebleau, France, to the English-speaking world. Watson spent a summer visiting Matheron in 1972.

Much of his working life was spent at Princeton University; he arrived in 1970, to head the Department of Statistics, a position he held until 1985, and he retired from the university in 1992 as emeritus professor. While at Princeton, Geof became involved in energy and environmental issues such as estimating US oil and gas reserves, climate trends, and assessing the effects of air pollution on public health and the ozone layer.

An autobiographical account of his life and research is given in two chapters of the edited book, *The Art of Statistical Science: A Tribute to G.S. Watson*, published in 1992. Geof was an accomplished watercolor painter; during his retirement until his death in 1998, he had shown his work in several solo shows in Princeton art galleries. His personality was unique, coming from a palette of Australian, British, and US influences.

Wavelets in Geosciences

Guoxiong Chen¹ and Henglei Zhang²

¹State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan, China

²Institution of Geophysics and Geomatics, China University of Geosciences, Wuhan, China

Definition

Wavelets (or wavelet transform) are a series of mathematical functions which can analyze nonstationary signal with both time and frequency resolutions. The fundamental idea behind wavelet transform is to analyze signals according to scale, by using the scaling and shifting transform of wavelet function. They decompose a signal into different frequency components that make it up, just like the Fourier transform, but also identify where a certain frequency or wavelength exists in the temporal or spatial domain. Wavelets have been endowed with many excellent properties for signal analyzing, including the time-frequency localization, multiresolution, compression (or sparsity), decorrelation, and so

on. Wavelets have therefore enjoyed a tremendous attention and success in Geosciences community, including, but not limited to, the applications of time-frequency analysis, multi-scale decomposition, filtering/denoising, and fractal/multifractal analysis.

Historic Wavelets Analysis

Wavelets have greatly fascinated the research in engineering, mathematics and nature science communities since 1980s because of the versatility in numerical analysis and function approximation. Its origin should be traced back to the Fourier transform theory that was pioneered by Joseph Fourier in 1807 to express signal as the sum of a, possibly infinite, series of sines. Fourier transform provides a powerful tool for analyzing stationary signals by converting them into frequency-domain, in order to explain the characteristics of frequency (or wavelength) of signals. As the most classical and successful signal processing and analyzing method, Fourier transform has achieved great success in both theory and applications in the past 200 years. However, it is theoretically only suitable for analyzing stationary signal without resolution of timescale, making them unavailable to realize the time-frequency localization analysis of nonstationary signal. For this reason, Gabor (1946) proposed the windowed Fourier transform, which has made substantial progresses in the aspect of time-frequency localization of signals, whereas it is often limited in the practical applications for analyzing complicated signals due to the lack of self-adaptability of time-frequency window. As a milestone in the development history of Fourier transform, wavelet transform (WT) has been a perfect achievement of functional analysis, Fourier analysis, harmonic analysis, and numerical analysis. WT overcomes many shortcomings of classical Fourier analysis, such as the limitation for analyzing nonstationary signal, the lack of time-frequency positioning ability and thus absence of time-frequency resolution. As such, wavelets have the reputation of “mathematical microscope” which can analyze nonstationary signals and capture many details of signals at multiscale time-frequency resolutions.

The initial concept of wavelet transform was first proposed by French geophysicists, Morlet and his colleagues (Morlet et al. 1982), with incentive to analyze and process seismic reflection signals in oil and gas exploration. They proposed the rudiment of wavelet analysis that uses shape-invariance property to overcome the shortcoming of windowed Fourier transform. Immediately, the powerful numerical analysis ability of Morlet’s method inspired many scholars, including Morlet himself, French theoretical physicist Grossman, French mathematician Meyer, and many others, to promote the rapid development of wavelet transform/analysis (e.g., Daubechies 1988; Grossmann and Morlet 1984;

Lemarié-Rieusset and Meyer 1986; Mallat 1989). In 1986, Meyer and his student Lemarie firstly proposed the fundamental idea of wavelet multiscale analysis. In 1988, Daubechies proposed the smooth orthogonal wavelet with compact support set-Daubechies basis which became one of the most widely used wavelet basis in WT. In 1989, Mallat proposed the concept of multiresolution analysis, the general method to construct orthogonal wavelet basis, and the famous Mallat algorithm of multiscale decomposition based on discrete wavelet transform. Sweldens (1995) developed the “promotion method” to construct the second-generation wavelets and made the construction of wavelets get rid of its conventional dependence on Fourier Transform. The fundamental theory of wavelet transform and analysis have been maturely developed in the last decade of the 20 century (Mallat 1999).

As wavelet analysis have many advantages over Fourier analysis in many aspects, including the time-frequency localization, multiresolution, compression, and decorrelation, its applications have achieved tremendous popularity and success in wide range of scientific fields such as mathematics, physics, chemistry, biology, earth science, and computer science. In the field of earth science, wavelet transform, as an advanced data and signal analysis tool, has remarkable achievements in various case studies, such as signal denoising/filtering and time-frequency analysis in seismic exploration data processing, multiresolution analysis of geophysical field (e.g., gravity and magnetic fields) and remote sensing image, hydrological or geological time series analysis, turbulence analysis, to name but few examples. It is worth mentioning that wavelet analysis has been used as powerful tool for multiscale analysis of fractal/multifractals which show emphasis on scale-invariant properties across scales, such as singularity detection (Chen and Cheng 2016; Mallat and Hwang 1992) and multifractal spectrum analysis (Arneodo et al. 1988; Chen and Cheng 2017). Overall, wavelets are essentially used to study non-stationary processes and signals in geoscience in two ways: (1) as a signal analysis tool to extract multiscale information or components of signals and (2) as a basis for representation or characterization of the signal/process.

Since wavelets is not a new theory or methodology anymore, and the theoretical developments of wavelets have been largely completed over the last two decades of the twentieth century, we will not present a full and in-depth theory description here. Several good handbooks (e.g., Mallat (1999), Percival and Walden (2000)) on wavelet theory are available and many readable papers (e.g., Kumar and Foufoula (1997)) with a good review of wavelet theory have been published. We do however describe some mathematical background of wavelet analysis in this paper, and also present some important applications of using wavelet analysis in geoscience research.

Concepts

Fourier Transform

The Fourier transform of a function $f(x)$ is formulated as

$$F(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} f(x) e^{-i\omega x} dx, \quad (1)$$

where ω is the angular frequency of the periodic function $e^{-i\omega x}$, and therefore $F(\omega)$ can represent the frequency content of the function $f(x)$. Using the inverse Fourier transform, the original function can be recovered by

$$f(x) = \frac{1}{2\pi} \int_{-\infty}^{\infty} F(\omega) e^{i\omega x} d\omega. \quad (2)$$

According to the form of Eq. (2), $f(x)$ can be regarded as the weighted sum of the simple waveforms $e^{i\omega x}$, where the weight at particular frequency ω is given by $F(\omega)$.

Although the Fourier transform built a bridge between the time and frequency domains, it has significant limitations in analyzing and processing nonstationary signals in several aspects. Specifically, the Fourier transform integrates the entire time domain and lacks local analysis capabilities; on the other hand, the instantaneous change of the signal (such as singularity) often affects the entire spectrum analysis. The short-time Fourier Transform (STFT) was developed to overcome above issues, and it is defined as (Gabor 1946)

$$STFT(\omega, x) = \frac{1}{2\pi} \int_{-\infty}^{\infty} f(u) w(u-x) e^{-i\omega u} du, \quad (3)$$

where $w(x)$ is the windowing function (e.g., Gaussian window), ω and u are frequency and translation (time) parameters, respectively. The Fourier transform of the segmented signal through $w(x)$ centered at $x = u$ then provides the position of frequency and extract local-frequency information of signal.

However, STFT cannot address the problem of adaptive adjustment of resolution units in practical applications because of the fixed resolution units defined in Eq. (3). There is an urgent need for the time-frequency window or resolution units that have an adaptive adjustment function when analyzing real signals. In detail, when analyzing the low-frequency components of the signal, the resolution unit or time-frequency window is automatically widened, and the ability of frequency localization becomes relatively weak. On the other hand, when analyzing the high frequency components of the signal, the resolution unit or time-frequency window is automatically narrowed, and the ability of frequency localization is improved. In short, an ideal method of time-frequency localization should have the function of “microscopy” that is scale independent.

Continuous Wavelet Transform

A wavelet is a wave-like oscillation with an amplitude that begins at zero, increases, and then decreases back to zero. A mother wavelet function is defined as

$$\psi(x) = \frac{1}{s^n} \psi\left(\frac{x-b}{s}\right), s > 0, x \in \mathbb{Z}^n, b \in \mathbb{Z}^n \quad (4)$$

where s is the scaling factor and b is a timescale like translation parameter. Note that L^1 – norm ($1/s$) is used in Eq. (4) for normalization. The continuous wavelet transformation (CWT) of a function $f(x) \in L(\mathbb{Z}^n)$ at scale a (related to frequency) and position b is given by (Grossmann and Morlet 1984)

$$Wf(s, b) = \frac{1}{s^n} \int_{-\infty}^{+\infty} f(x) \psi\left(\frac{x-b}{s}\right) dx \quad (5)$$

where $\psi_{s, b}$ defines a family of isotropic wavelets through translation and dilation of the mother wavelet $\psi(x)$. Eq. (5) can be further considered as a convolution product: $Wf(s, b) = f * \psi_s(b)$, and thereby the function $f(x)$ can be decomposed into elementary space–scale contribution by convolving it with a suit of mother wavelets, which are well localized in time and frequency space.

Wavelet transform provides a good solution for addressing the above-mentioned practical problems facing Fourier transform or STFT. Figure 1 shows a tiling of space–frequency plane defined by a 1D wavelet basis, which illustrates the shape of a wavelet resolution adaptively depends on the scale. As the scale decreases, the space support is reduced but the frequency spread increases. It is becoming clear that the

Wavelets in Geosciences, Fig. 1 Multiresolution space-frequency tiling of wavelet analysis, illustrating the shape of a wavelet resolution adaptively depends on scale. (Chen and Cheng 2016)

resolution of wavelet transform can be improved adaptively for analyzing high-frequency signal, while it becomes poor for analyzing low-frequency signal. The zooming capability of the wavelet transform not only can help to locate isolated singularity events, but can also characterize more complex multifractal signals when possessing non-isolated singularities (Mallat 1999; Mallat and Hwang 1992).

Discrete Wavelet Transform

Like the discrete Fourier transform, the discrete wavelet transform (DWT) decomposes the signal into mutually orthogonal set of wavelets using a discrete set of wavelet basis with scales a and translations b . This specificity represents the main difference between CWT and DWT. In practical, the DWT often employs a dyadic grid (Mallat 1999), where the mother wavelet is scaled by power two ($a = 2^j$) and translated by an integer ($b = k2^j$), where k is a location index running from 1 to $2^j N$ (N is the number of observations) and j runs from 0 to J (J is the total number of scales).

Through defining the dyadic mother wavelet as:

$$\psi_{j,k}(x) = 2^{-j/n} \varphi(2^{-j}x - k) \quad (6)$$

we can obtain the DWT coefficients using the following expression

$$W_{j,k} = W(2^j, 2^j k) = 2^{-j/2} \int_{-\infty}^{+\infty} f(x) \psi(2^{-j}x - k) dx \quad (7)$$

On the other hand, the original signal (or its parts) can be reconstructed from the wavelet coefficients by means of the Inverse Discrete Wavelet Transform (IDWT), which is formulated as

$$f(x) = \sum_{j=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} W_{j,k} \psi_{j,k}(x) \quad (8)$$

The DWT supports different mother wavelets, such as Harr, Daubechies, Biorthogonal, Symlet, Meyer, and Coiflets. The Haar wavelet is the first and simplest mother wavelet, and the Daubechies (Db) wavelet is a family of orthogonal wavelets, where Db1 is similar to Haar wavelet. A proper wavelet should be chosen for real signal analysis, which often depends on the similarity between wavelets and signal.

Applications Review of Wavelets in Geosciences

Wavelet transform or analysis has been widely used in many aspects of geoscience research for the past decades. In this section, we only present several interesting applications of using wavelets in geoscience (e.g., multiscale decomposition,

multifractal analysis, time-frequency analysis, filtering/denoising, etc.) as reviewing all of them in a couple of pages is certainly not possible, and hopefully will be a source of inspiration for new research.

Multiresolution Analysis/Decomposition

An essence of WT is “to see the wood and the trees,” in other words, to obtain multiscale natures of signals through the wavelet-based multiscale decomposition (WMD) algorithm. The classic framework of WMD is introduced by Mallat(1989) to project signal $f(\mathbf{x})$ onto a set of basis $\left\{ \varphi_{J,k}(\mathbf{x}), \left\{ \psi_{J,k}^{(i)}(\mathbf{x}) \right\}_{j \leq J} \right\}, j \in \mathbb{Z}^n, \mathbf{k} \in \mathbb{Z}^n, i = 1, 2, \dots, 2^n - 1$, where

$$\varphi_{J,k}(\mathbf{x}) = 2^{-j/n} \varphi(2^{-j}\mathbf{x} - \mathbf{k}) \quad (9)$$

and

$$\psi_{J,k}^{(i)}(\mathbf{x}) = 2^{-j/n} \psi^{(i)}(2^{-j}\mathbf{x} - \mathbf{k}) \quad (10)$$

are obtained by dilating and translating the mother wavelet $\psi(\mathbf{x})$ and father wavelet (scaling function) $\varphi(\mathbf{x})$ with the special choice $a = 2^j$ and $b = 2^j \mathbf{k}$ for discretization, respectively. The WMD is realized using a simple scheme, the so-called pyramid algorithm (Fig. 2). More details about the WMD algorithm can be found in Mallat (1989). Hence, the signal $f(\mathbf{x})$ can be expressed as

$$f(\mathbf{x}) = \sum_{\mathbf{k} \in \mathbb{Z}^n} A_{\mathbf{k}} \varphi_{J,k}(\mathbf{x}) + \sum_{j=1}^J \sum_{\mathbf{k} \in \mathbb{Z}^n} \sum_i d_{j,k}^{(i)} \psi_{J,k}^{(i)}(\mathbf{x}) \quad (11)$$

Wavelets in Geosciences, Fig. 2 Pyramid architecture of the multi-resolution analysis. Details and approximations are progressively built in pyramid from up to scale j (Chen and Cheng 2016)

with $A_{\mathbf{k}} = \int f(\mathbf{x}) \varphi_{j,k}(\mathbf{x}) d\mathbf{x}$ and $d_{j,k}^{(i)} = \int f(\mathbf{x}) \psi_{j,k}^{(i)}(\mathbf{x}) d\mathbf{x}$ termed as approximation coefficient and detail/wavelet coefficient, respectively. For instance, the multiscale representation of 2D signal $f(\mathbf{x})$ up to scale J consists of a low-frequency approximation A_J and three high-frequency details $D_{j,k}^{(i)}, i = 1, 2, 3$ in horizontal-, vertical-, and diagonal direction.

In this entry, we present an application of wavelet analysis of geological time series data to determine the cyclicity of Earth's long-term evolution, such as Wilson cycle of plate tectonics - supercontinent assembly and breakup. The zircon U-Pb age peaks and evolved $\delta^{18}\text{O}$ isotopes in deep geological time are often linked to supercontinent assembly. The recently improved global database of U-Pb ages and $\delta^{18}\text{O}$ isotopes from zircon grains allows the time series periodicity analysis by a popular method of wavelet transform (see Chen and Cheng (2018), and references therein). In this section, wavelet-based multiscale decomposition is undertaken to decompose one dimensional (1D) time series signal of U-Pb age distribution into multiscale components including approximations and details. In practical, there exist a variety of wavelet families in WMD algorithm (e.g., Haar, Daubechies (db), symlets (sym), and Biorthogonal, etc.), and a proper wavelet should be determined for processing geochemical time series data. Three criteria may influence the choice of wavelets including number of vanishing moments, support size, and regularity (Mallat 1999). Considering the fact that the practical geochemical time series signal often presents complex or fractal natures, the regular orthonormal wavelets with higher compact support like db8 may be better choices for obtaining reasonable decompositions. Using the five levels in WMD, the raw U-Pb age time series signal was decomposed into multiscale components involving wavelet details at scale $j = 1, 2, 3, 4$, and 5, as shown in Fig. 3a-e, and wavelet approximation at scale $j = 5$ in Fig. 3f. The wavelet approximation signals could be regarded as smoothing (averaging) results of original signal because of the low-pass filtering of father wavelet in WMD. Superposition of Fig. 3a-f time series can recover the raw sedimentary record, while superposition of Fig. 3a-d could construct the new signal without background interference, i.e., detrended time series. Also shown in Fig. 3g-k are Fourier spectrum analysis of each wavelet detail components, and they identified the periodicity of each detail components of U-Pb age distribution, ranging from 100 Myr to 800 Myr, related to global and continental-scale plate tectonics. In addition, WMD is often used to extract multiscale natures (including components and edges) of two-dimensional image or fields (e.g., Chen et al. 2015; Fedi and Quarta 1998).

Fractal/Multifractal Analysis

Wavelet transform acts as a natural tool for investigating the interscale relationship of fractal measures (e.g., scale-free,

Wavelets in Geosciences, Fig. 3 (continued)

self-similarity and singularity) because of the inherent scaling property of wavelet basis (Arneodo et al. 1988). Using wavelet or detail coefficients, the scaling behavior (i.e., Hurst exponent h) of singular increment function: $|f(x + \Delta I) - f(x)| \propto |\Delta I|^{h(x)}$, can be expressed as (Argoul et al. 1989)

$$W_\psi(\lambda s, x) \propto \lambda^{h-n+1} W(s, x) \quad (12)$$

On the other hand, the scaling behavior (i.e., singularity index α) of fractal clustering measure: $\mu(\epsilon) = \int_{B(\epsilon)} d\mu \propto \epsilon^{\alpha(x)}$, can be mirrored by scaling or approximation coefficients as (Chen and Cheng 2016)

$$W_\varphi(\lambda s, x) \propto \lambda^{\alpha-n} W(s, x) \quad (13)$$

where s represents the scale, λ represents the scalar number and n is the dimension of dataset. Notably, within the context of fractals, the Hurst index h characterizes the persistence or intermittency of time series, while the singularity index α characterizes the clustering or accumulation of mass or energy. Therefore, the wavelet transform provides an appropriate framework for both local Hurst detection (LHD) and local singularity analysis (LSA) of fractal signals or fields.

Moving forward, utilizing the inherent scaling property of the wavelet basis, the classic multifractal spectrum analysis based on box counting also can be revisited in wavelet forms. Accordingly, the power-law scaling relation defined in Eq (13) can be written as fractal density model when using approximate coefficients of DWT (Chen and Cheng 2016), namely $A(j) \propto (2^j)^\alpha - n$. As such, the mass-partition function of the q -th moment routinely used for multifractal spectrum calculation can be revisited as (Chen and Cheng 2017)

$$\chi_p(j, q) = \frac{1}{N_j} \sum_{k=1}^{N_j} [A(j, k)]^q, (-\infty < q < +\infty) \quad (14)$$

where N is the total number of scaling coefficients at level j . The DWT is generally implemented using a dyadic decimation (or down-sampling) scheme, the so-called Mallat's algorithm. These functions are built recursively in the space-scale half-plane (i.e., dyadic tree) of the orthogonal wavelet transform (see Fig. 1), cascading from an arbitrary given large scale toward small scales. Above wavelet-based strategy for implementing multifractal spectrum analysis employs the fast multiscale decomposition algorithm and the sparsity of wavelet representation; therefore, it would be less time-consuming

compared to conventional method especially for analyzing large datasets.

Figures 4a, b show the local singularity sequence of the zircon U-Pb age distribution and $\delta^{18}\text{O}$ isotope time series, respectively. Also shown in Figs. 4e, f are the point-wise Hurst sequences. Both indices were estimated using the multi-scale wavelet method. The local singularity indices representing the clustering of zircon ages identify the peaks and troughs in detail, while the point-wise Hurst index characterizes the persistence of adjacent values within the series. Six statistically significant peaks at approximately 4.1, 3.4, 2.6, 1.8, 1.0, and 0.2 Ga were observed in both Fig. 4a, b for the U-Pb age spectra and $\delta^{18}\text{O}$ analyses, and relatively smaller peaks at approximately 3.7, 2.5, 2.1, 1.4, 0.8, 0.6, and 0.1 Ga were detected in the zircon age spectra. In particular, the peak around 2.7-2.5 Ga, which was subdued in the raw $\delta^{18}\text{O}$ pattern was significantly amplified in Fig. 4b. Consequently, the estimated peaks of the age clusters and $\delta^{18}\text{O}$ values and their extents correspond well with supercontinent assembly periods at approximately 2.7-2.5 Ga (Superia and Sclavia), 2.1-1.7 Ga (Nuna), 1.3-0.95 (Rodinia), 0.7-0.18 (Gondwana and Pangea). In addition, the Hurst sequences (Fig. 4e, f) obtained from the zircon age distribution and $\delta^{18}\text{O}$ time series also reveal periodic patterns over 4.4 Gyrs. The higher Hurst values indicate the strong persistence of the time series (for U-Pb age signal it may imply a continuous growth of continent), while the lower values indicate a weaker persistence, where $h = 0$ implies an interrupted time series value. In particular, the timing of valleys within the Hurst sequence mark the beginning and end of supercontinent development well (see Fig. 4e, f). Both the singularity and Hurst series indicate the geological time series have a highly episodic nature from a fractal perspective, but the time series periodicity requires further quantitative evaluation.

Time-Frequency Analysis

Wavelet analysis allows a rapid detection of periodic patterns and the determination of persistence of cycle across time. According to the form of Eq. (5), a discrete time series $x(t_i)$ of length N with sample spacing Δt can be transformed into wavelet coefficients in both time and frequency domains by

$$W(s) = \frac{\Delta t}{\sqrt{s}} \sum_{j=0}^{N-1} x(t_j) \psi(\Delta t(j-i)/s), \quad (15)$$

Wavelets in Geosciences, Fig. 3 Multiscale decomposition of U-Pb age time series using wavelet-based multiscale decomposition algorithm. (a-e) represent multiscale wavelet details at scale $j = 1, 2, 3, 4, 5$, and (f) represents approximation or residual component.

Superposition of (a-f) time series can recover the raw sedimentary record (L). Also shown in (g-k) are Fourier spectrum analysis of each wavelet detailed components, and this identifies a dominant Wilson cycle of 600-800 Myr with minor cycles (~300, ~200, ~100, Myr)

Wavelets in Geosciences, Fig. 4 Local singularity analysis of (a) zircon U-Pb age database and (b) $\delta^{18}\text{O}$ isotope signal, and point-wise Hurst detection of (e) zircon U-Pb age and (f) $\delta^{18}\text{O}$ series (Chen and Cheng 2018a). Also shown in (c), (d), (g), and (h) are the continuous

wavelet spectrum of the singularity logs and Hurst logs of zircon U-Pb age distribution and $\delta^{18}\text{O}$ signal, respectively. The black dotted line represents the estimates of cyclicity determined on the basis of global wavelet power spectrum

where i represents the position shifting and s is the scale expansion factor. In fact, the above equation can be regarded as an enhanced version of the discrete Fourier transform in Eq. (2): $F(\omega) = \sum x(t_j)e^{i\omega t_j}$. The difference is that the periodic exponential $e^{i\omega t_j}$ is replaced by a wavelet function $\psi(t, s)$, and the advantage of wavelet functions is that they are well localized in both time and frequency space. There exists a series of wavelet function as diverse as Haar, Daubichies, Morlet, Mexican Hat, and so on. Among them, the Morlet wavelet is widely used because of the non-orthogonal and optimal joint time-frequency concentration, and its form is defined as

$$\psi(t) = \pi^{-1/4} e^{i\omega t} e^{-1/2t^2}, \quad (16)$$

where ω is dimensionless frequency. Although WT suffers from the Heisenberg uncertainty principle, the Morlet wavelet is a good choice for achieving a balance between time and frequency.

Wavelet coherence analysis (WCA) (also noted as wavelet cross-correlation analysis) is a method for quantifying similarity or coherency between two nonstationary series by using the localized correlation coefficients in time and frequency space (Torrence and Compo 1997). Given two time series X and Y , firstly, the wavelet cross-correlation transform is defined as

$$W_i^{XY} = W_i^X(s) \cdot W_i^Y(s). \quad (17)$$

Then wavelet coherence can be defined by

$$R^2(s) = |S(W_i^{XY}(s))/s|^2 / |S(|W_i^X(s)|^2/s) \cdot S(|W_i^Y(s)|^2/s)|, \quad (18)$$

in which S is a smoothing operator defined by the wavelet type used. R^2 takes a value between 0 and 1, which resembles the implication of traditional correlation coefficient.

Here, the CWT was used to determine the periodicity of the global zircon age distribution and $\delta^{18}\text{O}$ time series. When processing raw data, the trend in zircon preservation potential interferes with the continuous wavelet spectra which poses the significant problem for periodicity determination (Chen and Cheng 2018a). This tendency has been eliminated by LSA and LHD, as shown in Figs. 4(a) and (b), and the resultant singularity or Hurst consequences representing isolated fluctuations geological time series signals can be employed to explore the underlying periodicity quantitatively. As expected, the application of CWT to singularity and Hurst sequences (Figs. 4c, d, g, and h) yields clearer patterns with persistent power for period estimation. The results reveal three prominent cycles, i.e., ~ 200 Ma, ~ 400 Ma, and ~ 750 Ma for both the U-Pb age distribution and $\delta^{18}\text{O}$ signal. Specifically, the ~ 750 Ma cycle is persistent throughout geological time, indicating a secular change, while the less persistent cycles of ~ 400 Ma and ~ 200 Ma are mainly identified for the period < 3.0 Ga. Furthermore, we utilized the WCA method to investigate the correlation between the identified cycles of the two singularity sequences. The results shown in Fig. 5 indicate significant in-phase coherence for an ~ 750 Ma cycle between the two series throughout Earth's history. The in-phase coherence found here indicates synchronization between processes resulting in age peaks (e.g., intensive magmatism or supercontinent assembly) and $\delta^{18}\text{O}$ highs (e.g., continent reworking). Additionally, in-phase coherence was observed with 400–500 Ma periodicity after 1.5 Ga. The present time series analysis findings suggest that the Earth continent evolved with a main periodicity of ~ 750 Ma along a series of minor cycles (~ 200 and ~ 400 Ma) linked to Wilson cycle of plate tectonics (supercontinent assembly and breakup).

Filtering/Denoising

The compression (or sparsity) property of WT allows that, for most signals, a large fraction of signal energy can be captured by a few very large wavelet coefficients. Motivated by and capitalizing this property, wavelet thresholding filtering is designed by a way of thresholding coefficients via a pre-defined threshold (Donoho and Johnstone 1994). The general process of wavelet thresholding filtering can be expressed as (Chen and Cheng 2018b).

$$W = W(f), W_T = F(W, T), A = W^{-1}(W_T) \quad (19)$$

where W and W^{-1} are the wavelet transform and inverse transform, respectively, F is the thresholding function, and T is the threshold value. More specifically, the above wavelet filtering model can be summarized in three steps: (I) implement DWT on the data and obtain its wavelet coefficients, (II) determine a threshold and perform thresholding

(or shrinkage) on these coefficients, (III) implement the IDWT of these selected coefficients to obtain the filtered signal in the space or time domain. Therefore, the determination of the threshold value and the choice of threshold function are two key steps for wavelet thresholding filtering.

Threshold determination is a very important question as well as a crucial step in wavelet shrinkage. For example, in signal denoising, a small threshold may preserve too much noise, whereas a large threshold leads to a loss of signal, causing artifacts and blurred edges. While the idea of thresholding is simple and effective, finding an optimal threshold is not trivial. Wavelet statistics can provide critic information for addressing above question, and recent study suggests that wavelet coefficients yield fractal /multifractal distribution and offer a new scheme for threshold determination based on different self-similarities (Chen and Cheng 2018b). A vast literature has emerged over decades on signal denoising or image compression using nonlinear techniques, in the setting of additive white Gaussian noise, such as VisuShrink, SureShrink, and BayesShrink. In order to separate coefficients of different class, thresholding functions (e.g., hard-thresholding and soft-thresholding) are often used in wavelet denoising. Hard thresholding sets any coefficients less than the threshold to zero, which can be expressed as:

$$\hat{C} = \begin{cases} C & \text{if } |C| \geq T \\ 0 & \text{if } |C| < T \end{cases} \quad (20)$$

While in soft thresholding, the threshold is subtracted from any coefficient which is larger than the threshold, and the coefficients less than the threshold is threshold to zero. It is expressed as:

$$\hat{C} = \begin{cases} C - t & \text{if } |C| \geq T \\ 0 & \text{if } |C| < T \end{cases} \quad (21)$$

To avoid the discontinuity caused by using the hard-thresholding and the biased estimation caused by using the soft-thresholding, one could apply nonlinear thresholding given by:

$$\hat{C} = \begin{cases} C & \text{if } |C| \geq T \\ C \sin\left(\frac{\pi(|C| - 0.5T)}{t}\right) & 0.5T \leq \text{if } |C| < T \\ 0 & \text{if } |C| < 0.5T \end{cases} \quad (22)$$

where C is the wavelet coefficient, $\hat{C}$ is after thresholding, and T is the threshold value.

Here we simply present an application of using wavelet denoising to improving the resolution of seismic reflection

Wavelets in Geosciences, Fig. 5 Wavelet coherence analysis of singularity sequences between zircon U-Pb age distribution and $\delta^{18}\text{O}$ time series (Chen and Cheng 2018a). Right-pointing arrows indicate that the

two signals are in-phase while left-pointing arrows are for anti-phase signals. The white dotted line indicates possible distorted results due to edge effects of the time series

image in oil/gas exploration. Wave field separation is the premise and foundation for high-resolution seismic processing, imaging, inversion of lithology parameters, and attributes analysis. In most land seismic surveys, the complicated surface and subsurface geologic conditions, together with ambient noise interferences, would produce strongly random noise in raw seismic reflection data, leading to the low signal to noise ratio, which could obscure important reflector information. Figure 6a shows the original seismic section from the

survey area, which has strong interference and low signal-to-noise ratio. Figure 6b shows the section processed by using the wavelet denoising. It can be observed that the wavelet thresholding method can reduce noise to some extent. Figure 6a, b show the spectrum analysis results of original data and the wavelet denoised data on the 50th trace. The result indicates that the denoising using wavelet transform can suppress the random noise drastically with the precondition of maintenance for the effective seismic wave. Although the

Wavelets in Geosciences, Fig. 6 Wavelet denoising. (a) The original seismic reflection image, (b) clean seismic image after wavelet denoising, (c) the power spectrum of seismic signal on the 50th trace, and (d) that after wavelet denoising

wavelet transform has been widely used for seismic data denoising, it can only detect in horizontal, vertical, diagonal, and several other limited directions when 2-D wavelet transform is used to process image data; thus most of the linear and even anisotropic characteristics in the signal cannot be well described. Recently, many advanced and powerful wavelet-derived techniques have been developed to improve denoising, e.g., the ridgelet transform, curvelet transform, and contourlet transform.

Others

Wavelet Neural Networks: WNNs are a new class of networks that combine the classic sigmoid neural networks and the wavelet analysis (Zhang et al. 1995). Wavelet transform is good at time-frequency localization analysis, while neural network has good self-learning function and fault-tolerant ability. In WNNs, the classic sigmoidal family of neural networks was replaced by wavelets as activation functions. Therefore, neural networks using wavelets as basis functions are particularly efficient in learning from sparse data, because WNNs adapt the scheme of multi-resolution analysis. Overall, WNNs have more flexible function approximation, stronger model recognition ability and higher tolerance of errors, while it will be less time-consuming compared to the classic ANN. More details of WNN methodologies can be referred to excellent reviews (Alexandridis and Zaprani 2013). WNNs have been used with great success in a wide range of applications in geosciences, including time series prediction, signal classification, and data compression. More recently, the wavelets have been utilized to develop new architecture of deep learning (deep neural network), such as wavelet convolutional neural network, which can capture both spatial and spectral features.

Wavelet Compression: Apart from its original intention of analyzing nonstationary signals, wavelets have been most successful in data and image compression applications (Shapiro 1993). The idea behind wavelet compression is based on the sparsity property of the wavelet coefficients,

and regular signal component can be recovered using a small number of wavelet approximation coefficients (at a suitably chosen level) and small part of the wavelet detail coefficients. In practical, wavelet compression offers an approach that allows reducing the size of data/signal while at the same time improving its quality through denoising the high-frequency components.

Conclusions

Wavelet analysis has enjoyed a tremendous success in geoscience research over the last decades, as wavelets provide a very simple and efficient mean of analyzing nonstationary signals that are often encountered in wide range disciplines of geosciences. So what is next? Theoretically, wavelets are not optimal for nonpoint singularity in higher dimensions since they have isotropic properties and only provide optimal approximations for (zero dimensional) point singularity. In the last decade, multiscale geometric analysis, as the development of wavelet theory, can deal with the singularity and anisotropy of high-dimensional data more effectively. Up to now, there are many new achievements in multiscale geometric analysis, including ridgelet transform (Do and Vetterli 2003), curvelet transform (Starck et al. 2002), contourlet transform (Do and Vetterli 2005), and shearlet transform (Easley et al. 2008), to name but few examples. All in all, considering the endless variety of nonstationary and/or anisotropic signals and processes that are commonly encountered in engineering and nature science, it is not difficult to estimate that there will be wider search for new fields of wavelet theories and applications.

Wave-Number Filtering

Sid-Ali Ouadfeul¹ and Leila Aliouane²

¹Algerian Petroleum Institute, Sonatrach, Boumerdes, Algeria

²LABOPHT, Faculty of Hydrocarbons and Chemistry, University of Boumerdes, Boumerdes, Algeria

Definition of the Wave-Number

In physics, the wave-number also known as propagation number or angular wave-number is defined as the number of wavelengths per unit distance the spatial wave frequency and is known as spatial frequency. It is a **scalar quantity** represented by k and the mathematical representation is given as follows:

$$k = 1/\lambda$$

where

- k is the wave-number
- λ is the wavelength

Wave-number equation is mathematically expressed as the number of the complete cycle of a wave over its wavelength, given by –

$$k = 1/\lambda$$

where

- k is the wave-number, and its unit is (1/m)
- λ is the wavelength of the wave in meter

The 2D Wave-Number

In the space (x,y) , the vector wave-number (k) has two components K_x and K_y :

$$k = k_x u_{k_x} + k_y u_{k_y} \quad (1)$$

where u_{k_x} and u_{k_y} are the vector units in k_x and k_y directions.

The modulus of the vector wave-number is

$$|k| = \sqrt{k_x^2 + k_y^2} \quad (2)$$

Wave-Number Calculation

Let $S(x)$, $x \in \mathbf{R}$ is signal, x presents the space (abscissa), $S(x)$ content on wave-number $F(k)$ is calculated using the 1D Fourier transform:

$$F(k) = \int_{-\infty}^{+\infty} S(x)e^{-2\pi j k x} dx = A(k) + jB(K) \quad (3)$$

The spectrum of amplitude is:

$$|F(k)| = \sqrt{A(k)^2 + B(k)^2} \quad (4)$$

In the 2D domain, the wave-number content is calculated using the 2D Fourier transform, let $S(x, y) \in \mathbf{R}$ a signal; x, y present the space, the wave-number content is obtained using the 2D Fourier transform:

$$\begin{aligned} \mathbf{F}(k_x, k_y) &= \iint_{-\infty}^{+\infty} s(x, y)e^{-2\pi j x k_x - 2\pi j y k_y} dx dy \\ &= A(k_x, k_y) + jB(k_x, k_y) \end{aligned} \quad (5)$$

The spectrum of amplitude is the modulus of $\mathbf{F}(k_x, k_y)$:

$$|F(k_x, k_y)| = \sqrt{A(k_x, k_y)^2 + B(k_x, k_y)^2} \quad (6)$$

Wave-Number Filtering

The wave-number filtering of a given signal $S(x)$, $x \in \mathbf{R}^n$, $n = 1, 2$ is an elimination of wave-number components of the signal; this can be done by a multiplication of the signal in the wave-number domain by a transfer function $F(k)$, $k \in \mathbf{R}^n$, $n = 1, 2$. In the space domain, the wave-number filtering is a convolution of the signal $S(x)$ with the transfer function $F(x)$.

Let $F(x)$, $x \in \mathbf{R}^n$, $n = 1, 2$ the transfer function of the filter, the wave-number filtering is:

$$FS(x) = \iint_{\mathbf{R}^n} S(\theta)F(x - \theta)d\theta \quad (7)$$

Where $\theta \in \mathbf{R}^n$, $n = 1, 2$.

$FS(x)$: is the filtered $S(x)$

In the wave-number domain, the spectrum of the filtered $FS(x)$, $FFS(K)$ is given as follows:

$$FFS(K) = FT[S(x)]^* FT[F(x)] \quad (8)$$

Where FT is the Fourier transform.

*Denotes the product.

Examples of Wave-Number Filter

The Butterworth Filter

The Butterworth filter is a type of signal processing filter designed to have a frequency or wave-number response as flat as possible in the passband. It is also referred to as a maximally flat magnitude filter. It was first described in 1930 by the British engineer and physicist Stephen Butterworth in his paper entitled “On the Theory of Filter Amplifiers” (Weinberg and Slepian 1960).

$$G(k) = \frac{1}{\left(1 + \left(\frac{k}{k_c}\right)^n\right)} \quad (9)$$

n is the number of poles in the filter.

k_c : is cutoff wave-number.

Figure 1 shows the graph of the transfer function of the Butterworth with different number of poles.

The Chebyshev Filters

Chebyshev filters are analog or digital filters having a steeper roll-off than Butterworth filters and have passband ripple (type I) or stopband ripple (type II). Chebyshev filters have the property that they minimize the error between the idealized and the actual filter characteristic over the range of the filter, but with ripples in the passband. This type of filter is named after Chebyshev because its mathematical

Wave-Number Filtering, Fig. 1 Graph of the transfer function of the Butterworth filter with the number of poles ($n = 3, 5$, and 7)

characteristics are derived from Chebyshev polynomials. Type I Chebyshev filters are usually referred to as “Chebyshev filters,” while type II filters are usually called “inverse Chebyshev filters” (Weinberg and Slepian 1960).

The bandpass ripple transfer function is (Daniels 1974):

$$G(k) = \frac{1}{\sqrt{1 + \epsilon^2 T_n^2\left(\frac{k}{k_0}\right)}} \quad (10)$$

where ϵ is the ripple factor, k_0 is the wave-number cutoff, and T_n is a Chebyshev of the n order.

The transfer function of inverse Chebyshev filters is (Williams and Taylors 1988) (Figs. 2 and 3):

$$G(k) = \frac{1}{\sqrt{1 + \epsilon^{-2} T_n^{-2}\left(\frac{k}{k_0}\right)}} \quad (11)$$

The Gaussian Filter

A Gaussian filter is a ► [filter](#) whose impulse response is a [Gaussian function](#) (or an approximation to it, since a true Gaussian response would have [infinite impulse response](#)). Gaussian filters have the properties of having no [overshoot](#) to a step function input while minimizing the rise and fall time. This behavior is closely connected to the fact that the Gaussian filter has the minimum possible [group delay](#) (Lutovac et al. 2001).

$$G(x) = \frac{1}{\sigma\sqrt{2}} e^{-\left(\frac{x}{\sqrt{2}\sigma}\right)^2} \quad (12)$$

In the wave-number domain, the transfer function of the Gaussian Filter is:

$$FG(k) = e^{-\left(\frac{k}{\sqrt{2}}\right)^2} \quad (13)$$

where σ is the standard deviation.

In the 2D domain the Gaussian filter is defined as (Smith 2002):

$$G(x, y) = \frac{1}{\sigma\sqrt{2}} e^{-\left(\frac{x+y}{\sqrt{2}\sigma}\right)^2} \quad (14)$$

In the wave-number domain, the transfer function of the Gaussian Filter is (Fig. 4):

$$FG(k_x + k_y) = e^{-\left(\frac{k_x + k_y}{\sqrt{2}}\right)^2} \quad (15)$$

Application to Gravity Data

In this section, we show an example of 1D gravity Bouguer anomaly data filtering in the wave-number domain using a Gaussian filter. Figure 5 shows the graph of these data versus the longitude; the gravity profile is located in Algeria, and data of the International Gravimetric Bureau (BGI, <https://bgi.obs-mip.fr/>) are used. The 1D Fourier transform is used to calculate the wave-number content of the signal. Figure 6 shows the graph of the spectrum of amplitude versus the wave-number, while Fig. 7 shows the graph of the spectrum of amplitude in the wave-number interval $[0, 3 \text{ deg}^{-1}]$. We observe two slopes: the first is in the wave-number interval $[0, 0.3 \text{ deg}^{-1}]$, while the second is in the wave-number interval $[0.3-10 \text{ deg}^{-1}]$. The first Bouguer anomaly is called

Gaussian kernel

$$G_{\sigma} = \frac{1}{2\pi\sigma^2} e^{-\frac{(x^2+y^2)}{2\sigma^2}}$$

Wave-Number Filtering, Fig. 4 Transfer function of the Gaussian, left (1D) and right (2D) (Smith 2002)

Wave-Number Filtering, Fig. 5 Graph of the gravity Bouguer Anomaly (BA) of a profile located in Algeria

the regional anomaly; it is due to deep causative sources and is characterized by low wave-numbers, while the second is called the residual anomaly, which is due to shallow causative sources and is characterized by high wave-numbers.

A Gaussian low filter with cutoff wave-number $k_c = 0.3 \text{ deg}^{-1}$ used to attenuate high wave-number content is the Bouguer gravity anomaly. The filtered anomaly is presented in Fig. 8; we observe that the obtained anomaly is

smoothed, which demonstrates the absence of the high wave-number content in the signal.

Figure 9 shows the graph of the spectrum of amplitude in the wave-number interval $[0, 3 \text{ deg}^{-1}]$; it is clear that the spectrum of amplitude has no content of wave-numbers higher than 0.3 deg^{-1} , which demonstrates the friability of the filter.

**Conclusions**

Wave-number known as propagation number or angular wave-number is defined as the number of wavelengths per unit distance; 1D and 2D Fourier transforms are used to calculate the wave-number content of a given signal. Many

filters can be used for wave-number filtering, which consists of attenuating some wave-number components of a signal. In this chapter, we show an example of wave-number filtering of gravity Bouguer anomaly data; the filtering can be used to separate between shallow and deep causative sources.

Whitten, Eric Harold Timothy

John Cubitt
Wrexham, UK

Fig. 1 Eric Harold Timothy Whitten, courtesy of Prof. Whitten

Biography

Eric Whitten, known to his colleagues as Tim, started his career as a hard-rock geologist, specializing in the tectonics, petrology, petrography, and geochemistry of granite batholiths. Out of the mass of data generated in his studies arose an interest in the use of statistics and 3-dimensional modeling for analyzing and displaying geological data. Following the introduction of computers in the late 1950s, Tim saw the significant potential of this modern technology and he became one of the founding and preeminent specialists in the application of computers to the Earth Sciences. These two topics then formed the main strands of his subsequent multi-faceted career.

Tim was born on 26 July 1927 in Ilford and spent most of his formative years in SE England. After his schooling, Tim worked as a clerk in London during WWII. He then went to University and earned a BSc in Geology from Kings College, London, in 1948 and a PhD in Geology from the University of London in 1952. Subsequently, he was awarded a DSc in Geology from the same university in 1968.

His career in the geological sciences started as a Lecturer in Geology at Queen Mary College, London (1948–1958) and, after emigration to the USA, continued as Professor of Geology at Northwestern University in Illinois (1958–1981) where he was Chairman of the Department from 1977 to 1981.

Moving to the Michigan Technological University in 1981, he joined the administrative arena as, Vice-President for Academic Affairs and Professor of Geology, from 1981 to 1988, and, after the role was renamed, Provost from 1988 to 1990.

He moved back to the UK in 1990 to the village of Widecombe-in-the-Moor on the granite batholith that forms the National Park of Dartmoor in the County of Devon. Here, apart from undertaking a few projects and writing technical articles, he has indulged his interests in sailing, ancient map collecting, and conducting research on local history, especially of Widecombe and Devonshire. Notably, Tim has been Treasurer of Widecombe Fair Committee Co. Ltd., for 14 years (on their Board for 25 years), Commodore of the Royal Western Yacht Club of England, and recently Vice-Chair of the Widecombe History Group.

By the time of his retirement, Tim was widely recognized as an authority on granite batholiths and the application of statistics and 3-dimensional visualization to the Earth Sciences. As a result, he has received a number of medals and awards including the Daniel Pidgeon Fund of the Geological Society of London in 1954, the William Christian Krumbein Medal of the International Association for Mathematical Geology in 1989 and the Geologists Association's Fullerton Award in 1996.

He was instrumental in the establishment of the International Association of Mathematical Geologists, as a Founding Member in 1968, and played an active role for many years including Secretary-General from 1976 to 1980, and President, from 1980 to 1984.

He has published prolifically with 114 professional contributions in the form of books, journal articles, abstracts, and reports.

Tim was married and has five children. Sadly, his wife died in 2019.

Zadeh, Lotfi A.

Sydney, Sydney, NSW, Australia
Earth and Sustainability Science Research Centre, University
of New South Wales, Sydney, NSW, Australia

Fig. 1 Lotfi A. Zadeh. (From IEEE Engineering and Technology History Wiki (ETHW) – Copyright held by IEEE)

Biography

Lotfi A. Zadeh was an electrical engineer, well known for his seminal fuzzy sets theory (Zadeh 1965, see the entry “Fuzzy Set theory in Geosciences”) and fuzzy logic (Zadeh 1975). Zadeh was born on 4 February 1921, in Baku, Azerbaijan. In 1931, his family moved to Tehran, Iran, his father’s birthplace. After graduating from Alborz College, one of the renowned colleges in Iran, he joined the University of Tehran (UT). A year after he graduated from UT as an Electrical Engineer in 1942, he immigrated to the US, and in 1944 he entered the Massachusetts Institute of Technology (MIT). Two years later, in 1946, he received his M.S. degree in Electrical Engineering and then moved to the Columbia University in New York City as a Ph.D. candidate as well as an instructor in Electrical Engineering (Trillas 2011). He would teach several courses such as electromagnetic theory, system theory, information theory, circuit analysis, and sequential machines (IEEE History Center).

In his Ph.D. dissertation, he worked on a novel approach in frequency analysis of time-varying networks (IEEE History Center). In 1949, after graduation and receiving his Ph.D. in Electrical Engineering, he started a new position as an Assistant Professor at the same university and became an Associate Professor in 1953, then a Full Professor, in 1957. The years 1950 and 1952 are significant in his early scientific life, since he published two seminal papers with Prof. J. R. Ragazzini on Wiener’s theory of prediction, and sampled-data systems, respectively.

In 1959, Zadeh joined the University of California, Berkeley as a Professor at the faculty of Electrical Engineering Department. During this time, he mainly focused on linear systems and automata theory. In 1963 when he was named the chair of the department, the name of the department was changed to Electrical Engineering and Computer Sciences

(EECS). In 1991, when he became a Professor Emeritus, Zadeh continued his teaching and research activities and also served as the director of Berkeley Initiative in Soft Computing (BISC). Simultaneously, he held several other visiting positions at renowned research institutes such as MIT, Princeton, IBM Research Laboratory, and Stanford University (Zadeh's Berkely | EECS faculty page).

As a Fellow of the IEEE, AAAS, ACM, AAAI, and IFSA, Zadeh received many prestigious awards such as the IEEE Education Medal, the IEEE Richard W. Hamming Medal, the IEEE Medal of Honor, the IEEE Millennium Medal, the ASME Rufus Oldenburger Medal, the B. Bolzano Medal of the Czech Academy of Sciences, the Kampe de Fariet Medal, the Nicolaus Copernicus Medal of the Polish Academy of Sciences, the Egleston Medal, the Franklin Institute Medal, and the Silicon Valley Engineering Hall of Fame, in addition to 24 honorary doctorates (Zadeh's Berkely | EECS faculty page).

Zadeh was serving on 70 journals' editorial boards. He also published a large number of peer-reviewed papers, including over 200 single-authored papers, in a variety of disciplines in information/intelligent systems. His main fields of interest were systems analysis, decision analysis and information systems, possibility theory, computational theory of perceptions, and computing with words.

He published his groundbreaking theory on fuzzy sets in 1965 (Zadeh 1965), and afterward, he proposed the fuzzy logic (Zadeh 1975, 1996, 2004). Fuzzy logic has been extensively applied in a variety of fields even in geosciences such as mineral prospectivity mapping (Sadeghi and Khalajmasoumi 2015, see the entry "Fuzzy Set theory in Geosciences").

Zadeh passed away in Berkeley, California on 6 September 2017, and was buried in Baku.

Z-Transform

Sathishkumar Samiappan¹, Rajendra Mohan Panda¹ and B. S. Daya Sagar²

¹Geosystems Research Institute, Mississippi State University, Starkville, MS, USA

²Systems Science and Informatics Unit, Indian Statistical Institute, Bangalore, Karnataka, India

Definition

The Z-Transform is a technique commonly used to convert a discrete-time (DT) signal into its frequency domain representation. The Z-transform is useful to analyze discrete systems and their stability.

Z-Transform of a DT signal $x[n]$ is defined as

$$X(z) = Z\{x[n]\} = \sum_{n=-\infty}^{\infty} x[n] z^{-n} \quad (1)$$

Inverse Z-Transform

$$x[n] = Z^{-1}\{X(z)\} = \frac{1}{2\pi j} \oint_C X(z) z^{n-1} dz \quad (2)$$

where n is an integer, and z is a complex number represented by $Ae^{j\theta}$.

Introduction

Let us consider a discrete-time system with a transfer function H that takes a series of numbers as inputs ($x[n]$), one at a time. Based on the values of $x[n]$, H produces a series of numbers as output ($y[n]$) based on current and past inputs (Fig. 1).

Systems such as H are common in many areas such as signal processing and population dynamics. Using the

Z-Transform, Fig. 1 A typical discrete-time system

Z-Transform, Fig. 2 Plot of a DT signal $x[n]$

Z-Transform, $y[n]$ can be determined from $x[n]$ and H or the system H can be modeled based on $y[n]$ and $x[n]$. The Z-Transform will also help determine the stability and behavior of the system.

Z-Transform of a DT Signal

Consider a DT signal with a first non-zero value starting at $n = -1$, which is denoted by $x[n] = [a_1, a_2, a_3, a_4]$. By applying Eq. 1, the Z-Transform of the sequence $x[n]$ can be written as

$$X(z) = a_1 z + a_2 + a_3 z^{-1} + a_4 z^{-2} \quad (3)$$

A careful look at Eq. 3 reveals that the value of the sequence $x[n]$ at every instance n is multiplied by z^{-n} resulting in a polynomial (Fig. 2).

Z-Transform of an Impulse Signal

A unit impulse signal $\delta[n]$ has a value of 1 at $n = 0$ and has a value of zero at all other times (Fig. 3).

By applying Eq. 1, the Z-Transform of $\delta[n]$ can be written as $Z\{\delta[n]\} = Z^0 = 1$. The delayed version of $\delta[n]$ by N units is represented by $\delta[n-N]$ and corresponding Z-Transform $Z\delta[n-N] = Z^{-N}$. A delay $\delta[n]$ by N steps is equivalent to multiplying the Z-transform of $\delta[n]$ by Z^{-N} . This property is both simple and powerful because any sequence $x[n]$ can be written in terms of time-shifted $\delta[n]$. For example, the sequence in Fig. 2 can be written as

$$X[n] = a_1 \delta[n+1] + a_2 \delta[n] + a_3 \delta[n-1] + a_4 \delta[n-2] \quad (4)$$

Because of Eq. 4, the output of any DT system H can be computed by only knowing the output of the same system for $\delta[n]$. The output of the system H for the input of $\delta[n]$ is known as the impulse response ($h[n]$) of the system. The transfer function of the system H can be obtained by computing the Z-Transform of impulse response $h[n]$. i.e., $Z\{h[n]\} = H(z)$.

Stability of a System from Transfer Function $H(z)$

Since the Z-Transform of a sequence produces a polynomial, it is reasonable to assume that $H(z)$ will be a rational function

Z-Transform, Fig. 3 Plot of an impulse function

with a polynomial in the numerator and denominator. For example,

$$H(z) = \frac{q_1 Z + q_2}{P_1 Z^2 + p_2 Z + p_3} \quad (5)$$

Where q_s and p_s are coefficients of numerator and denominator polynomials, respectively. Using factorization and partial fraction decomposition, Eq. 5 can be written in the form of

$$\frac{b_i}{(z - c_i)^j} \quad (6)$$

Where c_i is called a pole and j is the highest order of denominator polynomial in Eq. 5. At pole values, the denominator of $H(z)$ becomes zero. Using geometric series, the system can be tested for stability. Detailed steps can be found on (Oppenheim and Willsky 1996).

Z-Transform in Geosciences

The Z-Transform has multiple applications in the fields of engineering and geosciences with low computational complexity. The Z-Transform technique has implications in studying rainfall-runoff processes in complex hilly watersheds (Rai and Upadhyay 2009) and in improving accuracy for time-discrete sequences (Sakrison et al. 1967). The Z-Transform-based Genetic Algorithm is used to image authentication technique in the frequency domain (Mandal and Khamrui 2012). The Z-Transform is also helpful in the prediction of periodical variable structure system behavior using minimum data acquisition time (Dobrucky et al. 2007). Weighted wavelet the Z-transform is shown to be effective for period analysis of unevenly sampled time-series data (Foster 1996). The Z-Transform is used in the numerical modeling of poroelastic and viscoacoustic wave equations (Jian-Guo et al. 2014; Xu 2019). The Z-transform is used to extract features from seismic wave data (Robinson 1968; Hanming et al. 2009; Shi et al. 2012).

Summary

The Z-Transform is a generalization of a discrete-time Fourier transform commonly used to evaluate digital filters with feedback. This transfer function of a discrete-time system can analyze discrete-time signals using simple hardware architecture. The Z-Transform can be applied to study signals and discrete-time systems in geophysics.

 Batch learning, 953
 Bath's law, 330, 331, 1474, 1483
 Bathymetry, 928
 Bayes generalized linear model (BayesGLM), 1322
 Bayesian analysis, 84
 Bayesian decision theory, 774
 Bayesian framework, 1023
 Bayesian inference, 795–796
 Bayesian inverse problems, 786
 Bayesian inverse theory, 65, 66, 69, 70
 Bayesian inversion, 674–675
 Bayesian linear formulation, 67
 Bayesian linearized AVO inversion, 69
 Bayesian linearized seismic inversion methods, 540
 Bayesian LISP-based systems, 38
 Bayesian maximum entropy (BME), 72
 chronotopologic domain, 73
 chronotopologic estimation, 75
 definition, 71
 knowledge bases, 72–73
 model, 1387
 in real word applications, 76
 in software, 76
 uncertainty assessment, 75
 versatility, 75–76
 workflow, 74–75
 Bayesian methods, 65, 147, 1059, 1381
 Bayesian networks, 36
 Bayesian statistics, 64
 Bayes' rule, 75, 645, 894
 binary map layer, 653
 single map layer, 651
 Bayes's theorem, 62–64, 649–650, 674
 definition, 61
 derivation, 63
 Baysian Monte Carlo Markov Chain (MCMC) approach, 400
 Behavior, 1053, 1638
 Benioff strain, 1478
 Berea sandstone, 1083, 1084
 Bernstein functions, 1377
 Bessel function, 716, 1349
 Best linear unbiased estimator (BLUE), 1415

- Best optimal predictor (BOP), 1365
 Beta distribution, 665, 1192
 Bhatnagar-Gross-Krook, 1466
 Bias, 437
 Bias-corrected and accelerated (BCa) approach, 1431
 Bias correction in goodness of fit tests, 1432
 Bicubic splines, 1406
 Bifurcation ratio, 25
 Big data, 166, 231, 233, 235, 237, 323, 498, 814–816, 1020, 1345
 context-aware data and resource for geoscience, 90
 data science approaches, 91
 definition, 85
 infrastructure and characteristics of, 87–88
 machine-readable FAIR metrics, 89
 management, 249
 open science and open data, 88
 smart data ecosystem for geoscience, 88–89
 Bilateral gamma distribution, 197
 Bilinear interpretation, 1242
 Bilinear unmixing, 739
 Binarization, 926
 Binary association indices, 1119
 Binary classification, 777
 Binary gain control (BGC), 49, 53
 Binary images, 92, 93, 903, 905, 907
 basic MM operators, 93
 filtering on, 93
 geodesic dilation/erosion, 93
 HMT, 93
 skeletonization, 93
